SCALES OF VARIABILITY AT STATION ALOHA

An educational research cruise conducted at Station ALOHA (A Long-term Oligotrophic Habitat Assessment) in June 2011 measured a suite of physical, chemical, and biological parameters on a Lagrangian approach, sampling over daily and diel cycles. Nutrient and suspended particulate stocks were largely invariable over the sampling period, but estimates of primary production varied by as much as 221 mmol C m⁻² d⁻¹. Bacterial production rates in the upper euphotic zone were 3-5 times lower than average, at 8.73 pM Leu hr⁻¹ and 4.53 pM Leu hr⁻¹ in light and dark respectively. Sinking particle flux measurements calculated from sediment traps deployed over 7 days were high compared to the Hawaii Ocean Time-series (HOT) dataset (1.5 σ over ALOHA mean state); we hypothesize we were sampling the decline of a diatom bloom, as evidenced by high particulate silica export (3.1 σ over ALOHA mean state) and low dissolved silica (~1.6 σ below ALOHA mean state). Time-series, like HOT, provide an essential context for irregularly spaced but ecologically relevant perturbations in addition to providing a platform in which to train young scientists and spark collaboration. COMPARATIVE GENOMICS OF RHODOBACTERACEAE SP. HIBM11 REVEALS METABOLIC SPECIALIZATION IN A COASTAL, MARINE ISOLATE

The planktonic, marine bacterium Rhodobacteraceae sp. HIBM11 is a member of the ubiquitous and versatile roseobacter lineage of the alphaproteobacterial family Rhodobacteraceae. Strain HIBM11 was isolated from surface seawater collected off the coast of Oahu, Hawaii in the subtropical Pacific Ocean, and its genome was sequenced using a 454 GS FLX Ti platform to 121x coverage. Analysis of the 3.1 Mb genome, comprising 3,182 protein-coding genes and 57 functional RNA genes, reveals strain HIBM11 to be a motile, DWSP-degrading, aerobic anoxygenic phototroph (AAnP). While members of the roseobacter lineage are typically considered ecological generalists, features of the strain HIBM11 genome indicate a more specialized lifestyle. Compared to 39 other roseobacter genomes currently sequenced, strain HIBM11 harbors a low number of both sugar and amino acid transporters and an unusually high number of antibiotic/drug and secondary metabolite transporters. We hypothesize that HIBM11 may rely on a more limited suite of substrates for growth, possibly in association with a reluctant phytoplankton host. (Abstract ID 12266)

TRANSFORMATION OF TERRESTRIAL POLYCARBOXYLATE COMPOUNDS: THE “FORGOTTEN” COMPONENT

Despite the significant studies done to understand the chemical transformation of terrestrially distilled organic matter (tDOM) to the open ocean, surprisingly little is known about the flux and transformations of carboxyl compounds that comprise a major fraction of tDOM. To date, most studies of the transport of tDOM have focused on the aromatic signatures. By studying the chemical transformation of HMW-DOM along a salinity transect, we observed a decrease in the carbon contribution of the carboxylic-rich alicyclic molecules (CRAM) component as we move offshore. However, a significant amount of the CRAM component could reach the open ocean, which could explain the high carboxyl content in both tDOM and deep ocean DOM. In contrast to what has been suggested previously, our combined results of 13C-NMR, 1H-NMR, and FTIR spectroscopy indicate that the CRAM component consists of at least two different components classes (aliphatic polycarboxyl and lignin-like compounds). The preliminary results of a long photo-oxidation experiment of Dismal Swamp DOP shows nearly constant ratio between tDOC and carboxyl carbon during the entire irradiation experiment, which indicates the potential of using polycarboxylate compounds as tDOM tracer. USING FLUORESCENCE SPECTROSCOPY TO INVESTIGATE THE TEMPORAL PERSISTENCE OF HYDROCARBONS IN THE WATER COLUMN FOLLOWING THE DEEPWATER HORIZON OIL SPILL

Fluorescence spectroscopy has been utilized for decades to characterize colored dissolved organic matter (CDOM) in the marine environment. More recently, researchers have used this method for the identification of complex aromatic mixtures. While many in situ fluorometers were used to collect water column data following the Deepwater Horizon spill, most of those instruments were tuned to wavelengths that might not clearly capture hydrocarbon signals indicative of petroleum. We utilized a Horiba benchtop spectrofluorometer to produce 3D excitation/emission matrix (EEM) spectra, which enabled the identification of fluorescence characteristics of petroleum hydrocarbons, in addition to CDOM signatures. Water samples were collected in May 2010 onboard the R/V Weatherbird II, and follow-up cruises were conducted in August and December of 2010 and in February and May 2011 to collect and analyze water samples from the DeSoto Canyon region to the northeast of the Deepwater Horizon wellhead. Individual EEMs as well as depth profiles of fluorescence intensities will be presented which will show the temporal changes in hydrocarbon signatures found in the northeast Gulf of Mexico in the year following the Deepwater Horizon spill. GLOBAL ESTIMATES OF EDDY MIXING RATES AND IMPLICATIONS FOR TRACER UPTAKE

Mesoscale eddies can influence the uptake of heat and tracers by driving an eddy-induced circulation (i.e., bolus transport). In the subtropical gyres, this eddy induced transport acts to partially cancel the downward Ekman pumping, modulating the rate that heat and tracers enter the ocean. The extent of this cancellation, and whether it is a significant effect, is heavily dependent on one’s assumptions about eddy diffusivity. We use satellite observations (AVISO) to quantify surface eddy mixing rates in the global ocean using the effective-diffusivity method of Nakamura. Large values (~3000 m²/s) in the subtropical gyres indicate that climate models may be underestimating the eddy-driven upwelling and therefore overestimating the rate of tracer uptake. THE USE OF NEXT GENERATION SEQUENCING AND BIOINFORMATICS PIPELINES TO BUILD INFORMATIVE ALLELIC NETWORKS FOR INFERRING DEEP-SEA MIGRATION.

With the growing capabilities of next generation sequencing, we are able to gather an enormous amount of data from single individuals. This is critical in deep-sea research where the number of individuals used for migration analysis is restricted by the difficulties of collecting samples. The study of migration in deep-sea systems is critical to understanding how patchy communities like seeps or hydrothermal vents are connected throughout space and time. The connectivity of these environments is one of the forefront considerations in the effort to conserve them during mining endeavors. Our bioinformatics pipeline will link SNP’s together to determine alleles for several thousand genes from a few individuals. These alleles are the equivalent of additional individuals in mitochondrial studies, and will enable us to infer migration and connectivity from sparsely sampled populations. To test the effectiveness of this approach we will employ it to build allicic networks for a species of limpet being analyzed by other molecular and bioinformatics methodology. By taking advantage of new high-throughput techniques we hope to overcome the issues that arise from sampling in the deep-sea. (Abstract ID 10039)

BOTTOMS UP! EXAMINING THE BASE OF THE FOOD WEB IN SHELF SEAS

Shelf seas are a key interface in the global carbon cycle, contributing significantly to ocean carbon fixation and acting as an export pathway for terrestrially-derived material. In shelf seas the fate of carbon fixed as particulate organic matter (POM) by primary producers is poorly understood. Here we examine the base of the shelf sea food web by examining suspended POM (sPOM) from the Irish and Celtic Seas. Physical water column characteristics directly impact organic sPOM composition. Hence, lipid biomarker and isotopic compositions show significant spatial variation across the shelf. Water column dynamics influence nutrient distributions as shown in nitrogen isotopes and lipid biomarkers. The strength of pelagic-benthic coupling is also reflected by these parameters. Close coupling in the mixed region of the Irish Sea is observed though isotope and biomarker properties. At the shelf break, internal mixing and nutrient upwelling influence community composition with zooplankton biomarker signals at the deep chlorophyll max (DCM) and heavier δ15N values than might be expected at the DCM. Changing physical conditions and their impact on sPOM distributions appear critical for ecosystems in shelf seas. (Abstract ID 10216)
The small size, short lifetime, and rapid advection of submesoscale phenomena present considerable observational challenges to both in situ and remote sensing measurements. Innovative measurement methods allow for the observation of submesoscale features, particularly spiral eddies in January 2010 and April 2011. Real-time ocean-surface radiative temperatures are recorded with both an airborne infrared camera and an altitude and heading reference system. A 10x20 km area is mapped consecutively in 2-3 hours to produce a georeferenced map of SST with high spatial (10 m) and temporal (10-15 min/track) resolution. Using multiple overpasses of the features and tracking algorithms, we derive surface currents on subsequent SST maps. The measurements are compared to sun glint images and interpreted in the context of the background mesoscale velocity field. Preliminary results confirm large rotational velocities and large Rossby numbers, indicating significant ageostrophic dynamics. (Abstract ID 12056)

USING NASAS GIOVANNI SYSTEM TO SIMULATE TIME-SERIES STATIONS IN THE OUTFLOW REGION OF CALIFORNIA'S EEL RIVER

Oceanographic time-series stations provide vital data for the monitoring of oceanic processes, particularly those associated with trends over time and interannual variability. There are likely numerous locations where the establishment of a time-series station would be desirable, but for reasons of funding or logistics, such establishment may not be feasible. An alternative to an operational time-series station is monitoring of sites via remote sensing. In this study, the NASA Giovanni data system is employed to simulate the establishment of two time-series stations near the outflow region of California's Eel River, which carries a high sediment load. Previous time-series analysis of this location (Ackler et al. 2009) indicated that remotely-sensed chl a exhibits a statistically significant increasing trend during summer (low flow) months, but no apparent trend during winter (high flow) months. Examination of several newly-available ocean data parameters in Giovanni, including 8-day resolution data, demonstrates the differences in ocean parameter trends at the two locations compared to regionally-averaged time-series. The hypothesis that the increased summer chl a values are related to increasing SST is evaluated, and the signature of the Eel River plume is defined with ocean optical parameters. REFERENCE: Ackler et al. (2009) Time-series analysis of remotely-sensed SeaWiFS chlorophyll in river-influenced coastal regions. EARSeL e-proceedings, 8(2), 114-139. (Abstract ID 11210)

USING THE NASA GIOVANNI DICCE PORTAL TO INVESTIGATE LAND-OCEAN LINKAGES WITH SATELLITE AND MODEL DATA

Data-enhanced Investigations for Climate Change Education (DICCE), a NASA climate change education project, employs the NASA Giovanni data system to enable teachers to create climate-related classroom projects using selected satellite and assimilated model data. The easy-to-use DICCE Giovanni portal (DICCE-G) provides data parameters relevant to oceanic, terrestrial, and atmospheric processes. Participants will explore land-ocean linkages using the available data in the DICCE-G portal, in particular focusing on temperature, ocean biology, and precipitation variability related to El Niño and La Niña events. The demonstration includes the enhanced information for educators developed for the DICCE-G portal. The prototype DICCE Learning Environment (DICCE-LE) for classroom project development will also be demonstrated. (Abstract ID 11251)

OCEAN OBSERVATORIES: EVOLUTION AND FUTURE DIRECTIONS

Ocean observatories (systems of coordinated ocean sensors and platforms providing real-time observations across multiple temporal and spatial scales) have advanced in complexity and purpose over several decades, integrating hardware, software, and people networks and employing fixed, drifting, and mobile components. These advances have provided interactive access to persistent, real-time, high-frequency, multi-disciplinary observations representing even the most extreme environmental conditions from the coast to the deep sea, resulting in unprecedented descriptions of ocean processes and inspired scientists and students to investigate increasingly complicated problems. Combined with traditional ship-based and remotely sensed observations, ocean observatories have yielded new knowledge across a broad scope of earth-ocean scales including global and regional circulation, ecosystem and carbon dynamics, air-sea interaction, ocean acidification, and ocean floor substrate-fluid processes. This overview will discuss the evolution of ocean observatories, summarize key science accomplishments, and muse about future directions. (Abstract ID 11170)

HIGH- TO LOW- FREQUENCY VARIABILITY OF MOORED TEMPERATURE, CURRENTS AND DISSOLVED OXYGEN ACROSS CENTRAL OREGON'S COASTAL OCEAN

Contrasts between inner- and mid-shelf dynamics drive cross-shelf variations of nutrient and water mass gradients and transport on the shelf. These contrasts are of central importance in the productive central-Oregon coastal upwelling environment where physical drivers such as wind-driven upwelling, tides, and diurnal forcing vary across the shelf, setting the stage for...
biogeochemical responses. Temperature, current and dissolved oxygen measurements from moorings deployed during the upwelling seasons of 2009-2011 off the central Oregon coast are analyzed to explore the relationship between mid-(70 m) and inner-shell (15 m) dynamics, and their effect on dissolved oxygen. Cumulative displacements calculated from overlapping current records (2009-75 days) paint a picture of a more wind-driven inner shell and a retentive mid-shell. Along-shell tidal current variations (K1) south of a submarine bank (Stonewall Bank) are similar between mid- and inner-shell sites and nearly three times higher than sites north of the bank. We also explore the relationships across frequency bands between inner-shell and nearby rocy intertidal zone temperature measurements to understand the tie between oceanic and local influences on intertidal measurements. COASTAL MONITORING PARTNERSHIP BETWEEN A UNIVERSITY SCIENTIST, A LOCAL HIGH SCHOOL, AND A MUSEUM USING THE BASIC OBSERVATION BUOY (BOB).

Partnerships between university scientists, local schools, and informal science centers can strengthen our coastal monitoring coverage; benefiting both the observing community and research programs of participating scientists as well as engage students and community members in the nature of science through data collection. Students learn first hand about environmental issues like the importance of water quality in our coastal ecosystems and the importance and role of technology in scientific research all while contributing data from their waterfront. These monitoring relationships often develop into community networks that positively affect all involved. Such a relationship began in 2010 between Kennesaw State University, Hilton Head Preparatory School, and the Coastal Discovery Museum, where students begin monitoring a local tidal creek using the Basic Observation Buoy (BOB). BOB is a small, inexpensive buoy made of PVC that can be assembled and deployed by students. The buoy is designed to serve as a platform for a suite of sensors that continuously measure parameters like temperature, pH, dissolved oxygen, and salinity levels in protected watersheds. Doug Levin designed BOB, while working at NOAA Chesapeake Bay Office in 2008. Due to the student friendly nature of BOB, COSESEF and SECOORA have adopted BOB and supported its growth and implementation throughout the east coast and great lakes. (Abstract ID 10677)

A SUBMERSIBLE OPTICAL VSF SENSOR WITH POLARIZATION

A new autonomous instrument that measures the VSF of water is described. It covers the entire frequency response of the optical sensor, and is designed for observation of water turbulence, and also for the global carbon cycle. The estimate of this parameter is still uncertain, and the processes that control aerosol Fe dissolution in seawater are poorly understood. Here we present dissolution experiment results from aerosols collected during the 2010 US GEOGRAFCES North Atlantic section cruise, and discuss the physicalchemical speciation of iron after dissolution and the influence of various leaching protocol vs. aerosol origin on dissolution estimates. IDENTIFICATION AND ANALYSIS OF INTERNAL POINCARÉ WAVES STRUCTURE IN LAKE MICHIGAN

Near-inertial internal Poincare waves are one of the dominant responses of Lake Michigan due to basin-wide wind forcing. Poincare waves tend to be ubiquitous over the whole basin, generating modes that resonate with the wind field. Since the wind field is composed of several frequencies, it generates several modes that span the basin. Data from field observations shows that vertical mode 1 and barotropic mode are the dominant modes in the vertical in the near-inertial (super-inertial) region. Identifying the horizontal modes of Poincare waves from field experiments is difficult, because of the difficulty in covering the whole basin. To address the role played by actual bathymetry, numerical simulations are carried out using the 3D hydrodynamic model SUTANS. Results showed generation of higher modes with time. In addition to highlighting currents and thermal variability induced by the Poincare waves, the associated distributions of cross-thermocline velocity shear and bottom stress are also investigated. Field data from various Lake Michigan field experiments are also compared with the numerical results. (Abstract ID 12331)

MERGING MULTI- & HYPER-SPECTRAL POLARIZED MEASUREMENTS FROM LONG ISLAND SOUND COASTAL OBSERVATORY: VALIDATION OF SATELLITE OCEAN COLOR SENSORS & IOP RETRIEVALS

To support present and future multi- and hyper-spectral calibration/validation activities for coastal waters for Ocean Color Radiometers (OCR) satellites, and for development of new measurement and retrieval techniques for coastal waters, City College along with the Naval Research Laboratory (Stennis) has established a scientifically comprehensive observation platform, the Long Island Sound Coastal Observatory (LISCO). LISCO uniquely combines a SeaPRISM, part of the NASA AERONET – Ocean Color Network, with a co-located a hyperSAS for multi and hyperspectral radiometer measurements. The efficacy of LISCO for satellite validation is evaluated for the three main OCR sensors, MERIS, MODIS and SeaWiFS, against datasets of quality-checked measurements of SeaPRISM and HyperSAS. It is shown that the merging of the multi spectral SeaPRISM and HyperSAS data significantly improves the overall data quality making LISCO highly suitable for satellite data validation purposes, as well as providing interpolation possibilities for wavelength coverage of gaps between SeaPRISM channels. Two recently added HyperSAS polarization channels, now permit polarized hyperspectral measurements of water leaving radiance, that are shown to provide insights to inherent optical properties and glint effects. (Abstract ID 11067)
SURFACE MASS TRANSFER IN LES OF LARGE SCALE AND SMALL SCALE LANGMUIR CIRCULATION

Surface scalar (mass) transport results from large-eddy simulation (LES) of wind driven flow with Langmuir circulation (LC) are presented. Wave-current interaction gives rise to Langmuir turbulence characterized by LC consisting of a spectrum of scales of counter rotating vortices roughly aligned in the direction of the wind. The typical crosswind length scale of the smallest observed vortices is on the order of several centimeters when the wind begins to blow over a quiescent interface and short capillary waves first appear. Large scale LC typically spans the upper ocean mixed layer depth. In shallow coastal shelves, large scale LC may engulf the entire water column. Two flows will be analyzed. The first flow is characterized by small scale (centimeter scale) LC and the second flow is characterized by large scale, full-depth LC in shallow water. Both flows exhibit increases in surface mass transfer velocity (efficiency) due to the presence of LC. Various parameterizations of surface mass transfer velocity will be evaluated by comparison with exact values obtained through direct measurement of vertical gradient of scalar concentration at the surface. (Abstract ID 12626)

INTER-ANNUAL SEA-SURFACE SALINITY ANOMALIES IN THE KURISHIO EXTENSION REGION ADVECTED FROM THE EAST OF THE PHILIPPINES

Sea-surface salinity variations in the Kuroshio Extension (KE) region are responsible for the salinity variation of the subtropical mode water that occupies a large part of the subsurface layer of the North Pacific subtropical gyre. By using the Argo data during 2004-2010, the salinity anomaly from the seasonal mean in the KE region was calculated. Tracing the region of the lag-correlation coefficient over 0.6 relative to the anomaly in the KE region, the anomaly in the top 100 m layer was found to be advected with a six-month elapsed time from the variation of the east coast of the Philippines to which the westward interior flow of the subtropical gyre is directed. Also, seven high-resolution hydrographic surveys across the KE During 2008-2010 were performed. The analysis of the data indicates that the salinity anomalies advected from the upstream region of the Kuroshio outcrop just south of the KE in winter. Through the advection and outcrop, the inter-annual salinity variation of the mode water is connected to that in the tropical region. (Abstract ID 9581)

LINEAR RELATIONSHIP BETWEEN CARBON AND NITROGEN ISOTOPE RATIOS ALONG SIMPLE FOOD CHAINS IN MARINE ENVIRONMENTS

To examine the relationship between carbon and nitrogen stable isotope ratios of zooplankton, we analyzed samples collected bimonthly from March to October 2009, from the A-line in the western North Pacific. Isotopic ratios of higher trophic levels such as predatory zooplankton and/or long-lived zooplankton varied little with season, while those of short-lived zooplankton were variable on the δ15N-δ13C map. We also analyzed preserved samples taken from the warm-core ring 86-B which derived from the Kuroshio extension region. Although the δ15N-δ13C slopes for each ecosystem do not show significant difference. Statistical analysis conducted together with previously published data from the Antarctic Ocean and the Gulf of Alaska suggested commonness in the δ15N slope throughout the four regions. We attributed this common slope to physiological aspects of feeding processes (e.g., the kinetic isotope effects inherent in the processes of amino acid synthesis). The common pattern for all four oceanic regions suggests that stable isotopes may be used to elucidate general patterns in ecosystems and biogeochemical cycles. (Abstract ID 10151)

THE ARCTIC BOUNDARY CURRENT FROM EDDY-PERMITTING AND EDDY-RESOLVING OCEAN MODELS
Observations and high-resolution eddy-resolving ocean models both suggest a fast flow along
the continental shelf in the Arctic Ocean. Thus far, this flow, termed the Arctic Circumpolar
Boundary Current (ACBC), has been seen as comprising the Fram Strait Branch (FSB) and
Barents Sea Branch (BSB). This study describes a new third branch, the Arctic Shelf Break
Branch (ASBB), forced by buoyancy loss and non-local wind that create high pressure
upstream in the Barents Sea. The potential vorticity influx through the St. Anna Trough
dictates the cyclonic direction of the ASBB. Numerical simulations show the continuity of
the ACBC all the way around the Arctic shelves. The ASBB is the most energetic large-scale flow
in the Arctic Ocean and transports Arctic halocline water, comparable in volume to the Bering
Strait inflow. The ASBB exhibits a robust seasonal cycle with a summer minimum and winter
maximum. The Alaskan Shelf Break Current (ASC) is analogous to the ASBB and is forced
by the local winds and by the drop in sea surface height between the Pacific and Arctic Oceans.

CALIBRATION AND VALIDATION OF MODIS-BASED OC3 MODEL FOR RED TIDE DETECTION AND MONITORING IN THE ARABIAN GULF
Red Tide occurrences in the Arabian Gulf have increased in the last few years. It damaged
the aquatic life and the economic side of the region. Red tide is the presence of algae blooms
(phytoplankton) which can be harmful, toxic and affects human health. MODIS (Moderate
Resolution Imaging Spectroradiometer) satellite, on board of Aqua and Terra satellites, has
been used recently to detect and map harmful algal blooms in different regions. Chlorophyll
concentrations and fluorescence measurements were collected at 3 different depths in 64
stations in the Arabian Gulf and the Gulf of Oman. This data was collected by ROMPS
Oceanographic cruise during a 24-day period in winter 2006. The collected data was used to re-
calibrate OC3 Model using both Aqua and Terra images. Different red tide related parameters
were derived: OC3-derived Chlorophyll-a concentration (μg m-3), fluorescence line height
(FLH W m-2 μm-1 sr-1), floating algae index (FAI), secchi desk (SD cm) and turbidity index
(TI). The correlations between these parameters were studied over the 20 selected stations.
High correlation was observed between chlorophyll-a concentration and turbidity index. The
effect of wind on the algal bloom activities near United Arab Emirates (UAE) coastline was also
studied during the cruise period. The short term variation of these parameters was also studied
by comparing morning (Terra) and afternoon (Aqua) scenes. (Abstract ID 10569)

SHEAR TURBULENCE BELOW THE BASE OF THE WELL-MIXED LAYER.
The well mixed layer in the upper ocean is maintained by mixing due to turbulence generated
by the action of wind, waves and buoyancy fluxes at the ocean surface. Scaling laws for shear
and convective turbulence are well established. More recently large-eddy simulation has been
used to establish scalings for Langmuir turbulence, that is generated through the action of
wave induced Stokes drift. Regions of shear and low Richardson number often occur below
the base of the mixed layer. These regions are frequently turbulent and have been considered
to form transition regions between the mixed layer and the underlying ocean. Turbulence in
these shear layers has been characterised by eddy diffusivities that are taken to be functions of
the Richardson number. In this presentation large-eddy simulation (LES) is used to investigate
the nature of turbulence in these shear layers. The results from the LES are used to develop a
scaling for the shear turbulence based on the surface stress and mixed layer currents. A key
feature of this scaling is that it assumes that the boundary layer spans both the well mixed and
shear layers. It will be shown that the length scale of the shear turbulence is consistent with
this assumption. The interaction between the well mixed layer and the shear layer will also be
considered. It will be shown that this can be described using a non-dimensional parameter
based on the rates of generation of mixed layer and shear turbulence. (Abstract ID 11070)

UNIVERSITY-NATIONAL OCEANOGRAPHIC LABORATORY SYSTEM- THE CURRENT AND FUTURE FLEET
The Town Hall meeting will present an overview of the University-National Oceanographic
Laboratory System (UNOLS) fleet as well as new ships under construction. Highlights will
include the R/V Sikuliaq currently being constructed on behalf of the NSF. This ship’s primary
mission will be to support scientific studies in high latitude waters. The 261 foot global class
general purpose oceanographic vessel will be capable of breaking 2.5 foot thick ice at 2 knots
with an endurance of 45 days at sea and cruising at 11 knots. The R/V Sikuliaq will carry 26
scientists and a crew of 20. The vessel design strives to have the lowest possible environmental
impact, including a low underwater-radiated noise signature. A projected launch date of June
2012, delivery to the University of Alaska Fairbanks in June 2013 and scientific operations are
planned to start in January 2014. The Office of Naval Research is also building two new Ocean
class ships joining UNOLS in 2014/2015. Details on these ships will also be highlighted Possible
science opportunities will be discussed and a question and answer period will follow. (Abstract
ID 11547)
In the lower estuary clay mineralogy consists of 70% expandable minerals and chlorite, an the transport and deposition of suspended particles from the inner estuary to the outer estuary. The seaward-increasing excess 210Pb to 137Cs activity ratio documents porosity, fine-grained layers, thinner in the inner estuary and thicker in the outer estuary, Anadyr fluvial sediments are typically coarse-grained, with sand >90% and mud <10%. R., Stanford University, Dept. Environmental Earth System Science, Stanford, CA, Arrigo@stanford.edu IRON AND LIGHT EFFECTS ON PHYTOPLANKTON PRIMARY PRODUCTIVITY IN THE AMUNDSEN SEA (ANTARCTICA) Phytoplankton primary productivity in the Southern Ocean is considered to be limited by the availability of Fe and/or light. The Amundsen and Pine Island Bay polynyas in the Amundsen Sea are areas with the highest phytoplankton primary productivity per surface area in the Southern Ocean. This region is affected by a rapid increase in melt rate of floating glacier termini and ice shelves in the Western Antarctic. These melting ice shelves were the major source of iron fueling the highly productive phytoplankton bloom dominated by Phaeocystis antarctica during the Austral summer of 2009. During the NBP1005 (ASPIRE) cruise in the spring of 2010/2011 we encountered another massive P. antarctica bloom (40 g m⁻² Chl a). Bioassay experiments revealed that iron additions increased photosynthetic productivity as well as nitrate uptake in surface phytoplankton, indicating that Fe availability may limit phytoplankton growth despite the large Fe input from melting ice shelves. Moreover, Fe additions increased photosynthetic efficiency at low light intensities, providing an additional positive effect of Fe input on photosynthetic productivity in high biomass areas where strong light attenuation reduces light availability. C., University of Miami, Miami, USA, Carlisle.Thacker@noaa.gov Omar Knio, O. M., Duke University, Durham, USA, knio@duke.edu UNCERTAINTY ANALYSIS AND QUANTIFICATION OF THE HYCOM SST RESPONSE TO HURRICANE IVAN USING POLYNOMIAL CHAOS EXPANSIONS The present study uses the method of Polynomial Chaos Expansion to quantify the HYCOM uncertainty in simulating the sea surface temperature response during the passage of Hurricane Ivan in the Gulf of Mexico. The sources of uncertainty were the values of the wind drag coefficient and those of 3 KPP mixed layer model variables. Sparse Smolyak quadrature was used to determine the PCE coefficients in this four-dimensional parametric space using an ensemble of 385 runs. The quality of the PCE representation was validated and than exploited to perform sensitivity and variance analyses, construct probability density functions, and compute the statistics of any quantity of interest without re-running the model. The model predicted an average cooling of 1 degree Celsius under Ivan's track with a standard deviation of 0.4 C, an estimate which is in-line with observations. The analysis showed that the main contributor to the uncertainty away from the storm was the background diffusion coefficient, a mixed layer variable, whereas the drag coefficient was the main contributor in the vicinity of the storm. The present application illustrates the efficiency of the PCE approach in exploring the entire parameter space and its usefulness in a posteriori sensitivity analysis. (Abstract ID 11881) Alexander, C. B., Stoddard Institute of Oceanography, Savannah, USA, clark.alexander@skios.usg.edu Windon, H. L., Stoddard Institute of Oceanography, Savannah, USA, hex.windon@skios.usg.edu Naidi, S. A., University of Alaska, Fairbanks, USA, sanaid@alaska.edu ESTUARINE PROCESSES IN THE ANADYR SYSTEM, CHUKOTKA, RUSSIA Geological and geochemical parameters, which can be used to track estuarine circulation processes, are examined in the Anadyr River and estuary in northeastern Siberia. Water and sediment samples from the Anadyr system were analyzed for texture, elemental geochemistry, natural and artificial radionuclides, POC/Chl a, clay mineralogy, and dissolved constituents. Anadyr fluvial sediments are typically coarse-grained, with sand >90% and mud <10%. In mud samples, silt dominates over clay. Estuarine samples, however, exhibit surficial, high-porosity, fine-grained layers, thinner in the inner estuary and thicker in the outer estuary, overlying firm sands. This distribution suggests that muds are delivered seasonally to the estuary and trapped there. The seaward-increasing excess 18O/16O or C13 activity ratio documents the transport and deposition of suspended particles from the inner estuary to the outer estuary. In the lower estuary clay mineralogy consists of 70% expandable minerals and chlorite, an assemblage distinctly different from the nearshore Bering Sea. The 8°C values (-25 to -27°C), reflect predominant terrigenous sources of POC. Our database suggests that the Anadyr estuary is an effective trap for fluvially derived material. (Abstract ID 12168) Alexander, M. A., NOAA/Earth System Research Lab, Boulder, USA, Michael.Alexander@noaa.gov Deser, C., NCAr, Boulder, USA, cdeser@ucar.edu Capotondi, A., University of Colorado/CIRES, Boulder, USA, Antonietta.Capotondi@noaa.gov Scott, J. D., University of Colorado/CIRES, Boulder, USA, James.D.Scott@noaa.gov THE INFLUENCE OF VARIABILITY IN THE NORTHERN PACIFIC AND TROPICAL WEST PACIFIC ON ENSO Vimont et al. (2001, 2003, J. Climate) proposed an extratropical-to-tropical connection termed the "seasonal fingerprinting mechanism" (SFIM), where internal fluctuations in the atmospheric circulation over the North Pacific during winter impacts a "footprint" on the ocean through changes in the surface heat fluxes. The SST footprint in the subtropical Pacific, impacts the atmospheric circulation including zonal wind stress and heat flux anomalies that extend into the western tropical Pacific in spring and summer. These anomalies can excite an ENSO response in the subsequent fall and winter. The heat content in the western equatorial Pacific also serves as a precursor to ENSO but is most effective in combination with SFIM-like anomalies (Anderson et al., 2006). Observations indicate that an anomalously deep thermocline in the western equatorial Pacific in summer, followed by anomalous westerlies over the subtropical North Pacific during winter, favors the development of El Niño events during the subsequent winter, 12-15 month after the initial thermocline anomalies. Here, we explore the joint impact of these precursors on ENSO using observations and CCSM4, NCAr's general circulation model. (Abstract ID 10940) Alfred, M. H., University of Washington, Seattle, USA, malford@apl.washington.edu Lukas, R., University of Hawaii, Honolulu, USA, rlukas@hawaii.edu Howe, B. M., University of Hawaii, Honolulu, USA, bhowe@hawaii.edu Pickering, A., University of Washington, Seattle, USA, apickering@apl.washington.edu Santiago-Mandujano, F., University of Hawaii, Honolulu, USA, mandujan@soest.hawaii.edu MOORED OBSERVATIONS OF EPISODIC ABBYSSAL FLOW AND MIXING AT STATION ALOHA Moored measurements of abyssal velocity and temperature are presented with a focus on episodic cold overflow events in the Hawaii Ocean Time-series (HOT), a 23-year-long time series of monthly CTD profiles at station ALOHA (22.75N, 158W). Three major cold events were observed in our 2.5-year record, of which we present one in detail. The event appeared in two pulses spaced by about two weeks, wherein potential temperature anomaly was < -0.015°C over the bottom 600 m. Flow was about 10 cm/s to the southwest, confirming earlier interpretations of the events as overflows from the Maui deep to the east. Between the two pulses, flow veered to the northwest, possibly associated with seiching. Speed decreased rapidly below the sill depth of about 4625 m, suggesting sheltering by the basin walls. The associated shear, even smoothed over 200 m and not including internal waves, was nearly unstable to Kelvin-Helmholtz instability. During this period, a large mixed region was observed wherein the temperature remained so for 14 hours (1.2 buoyancy periods). From Thorpe scale analysis, the implied diffusivity of the event was (0.5-4.5) x 10⁻⁸ m² s⁻¹. No other overturning events greater than 50 m high were observed in the record, suggesting that abyssal mixing is strongly intermittent. We suggest that such intermittency in abyssal mixing and flow is likely the rule rather than the exception. (Abstract ID 11628) Algar, C. K., Marine Biological Laboratory, Woods Hole, USA, calgar@mbl.edu Joseph Vallino, J. J., Marine Biological Laboratory , Woods Hole , USA, jvallino@mbl.edu A MAXIMUM ENTROPY PRODUCTION (MEP) BASED MODEL OF NITROGEN CYCLING PROCESSES IN LOW OXYGEN AND ANOXIC ENVIRONMENTS In low oxygen/anoxic environments re-mineralized nitrate may be lost as N₂ gas due to canonical denitrification and ANAMMox or it may be converted to ammonium by way of dissimilatory nitrate reduction (DNRA) and remain biologically available. As all three process are microbial mediated, a full understanding of nitrogen biogeochemistry in these environments requires an understanding of the functioning of the microbial ecosystem caring out these processes. Here we present a numerical model of nitrogen cycling based upon the principles of maximum entropy production (MEP), whereby the microbial community organizes in such a way so as to maximize its time integrated entropy production. Model simulations with varying carbon and nitrogen inputs, demonstrate switches between denitrification, ANAMMox and DNRA that are consistent with what has been observed in the natural environment. Simulations were also compared with results from a flow-through stable isotope labeling experiments. This work suggests that models based upon MEP theory may be a useful tool in predicting how microbial ecosystem functions and how the resulting biogeochemistry will respond to environmental perturbations of both natural and anthropogenic origin. (Abstract ID 11775)
High-resolution ocean–wave coupled modeling of the Adriatic Sea is explored using the Naval Research Laboratory’s state-of-the-art ESPM-based (Earth System Modeling Framework) Coupled Ocean and Atmospheric Prediction System (COAMPS). Recent advancements of COAMPS include the addition of both SWAN and WAVENUM3 components to the coupled system that allows full interaction of these wave models to both the atmosphere and the ocean model (NCOM). Ocean–wave interactions include the passing of NCOM ocean currents to the wave models and the wave models passing the Stokes’ drift currents, wave radiation stress gradients, and bottom stresses to NCOM. The validation period studied encompasses a portion of the DART (Dynamics of the Adriatic in Real-Time) field experiment that occurred in February–March 2006. Model comparisons to in-situ observations from several drifters and Acoustic Doppler Current Profilers (ADCPs) are analyzed to further our understanding of these ocean/wave model interactions and dynamic processes. ANOMALOUSLY STRONG TIDES IN THE GULFY, A SUBMARINE CANYON ON THE NOVA SCOTIA SHELF

Two major submarine canyons: Monterey Canyon off California and Gaoping Canyon off Taiwan, have strongly enhanced ocean tides. Tidal amplification theories include focusing, trapping and local generation of internal waves. A very similar canyon, The Gulpy off Nova Scotia is also observed to have these enhanced tides but with a significant difference. The enhanced tides in Monterey and Gaoping Canyons are the semi-diurnal tides whereas in The Gulpy the most strongly enhanced tides are diurnal and are thus sub-inertial. We will show observations of the tides and present two coupled wave theories that explain the enhanced sub-inertial tides in the Gulpy. Comparisons between theoretical properties of the amplified tides and observed properties support the applicability of the theories. Limitations and future enhancements of the wave theory will be discussed. (Abstract ID 11488)

DETECTING VIRAL INFECTION AT THE SINGLE CELL LEVEL WITH PHAGE FISH

Microbes drive the biogeochemistry that fuels our planet, and viruses cause 10-40% of microbial mortality in the ocean. In spite of this importance, interactions between microbes and their viruses (phages) remain poorly understood, primarily due to technological challenges. Here we apply gene-fluorescence in situ hybridization (gene-FISH, Moraru et al. 2010) to quantify the fraction of phage-infected host cells at the single-cell level, phosphate-FISH. Specifically, marine podovirus 10-kDa was introduced to one of its hosts, marine Pseudoalteromonas sp. H100 (Gannaproteobacteria) and monitored over time from phage entry to new assembly of phage particles using gene-FISH on phage and host genes. The fraction of infected cells and status of infection on the single-cell level (the phageFISH signal increases with increasing phage genome copy number) were validated against established population level metrics including the fraction of visibly infected cells by TEM, infective virus counts, and quantitative PCR of phage genes inside and outside of the host cell. Given the single-cell detection capability of gene-FISH, this work sets the stage for community level virus-host investigations that also detail cell-to-cell variability. (Abstract ID 10746)

HIGH-RESOLUTION SEAFLOOR AND SUBBOTTOM MAPPING OF UPPER MISSISSIPPI CANYON: RESULTS FROM THE 2011 UTIG MARINE GEOLOGY & GEOPHYSICS FIELD COURSE

UTIG annually offers a field course that provides student training in seismic data acquisition, processing, interpretation, and visualization. As part of the Year-4 field course, we surveyed upper Mississippi Canyon using high-resolution seismic reflection (air-gun), CHIRP sub-bottom profiling, multibeam bathymetry, and sidescan sonar. This survey revealed a significant sediment connection with the adjacent Mississippi River mouth. The steep wall zone of the
canyon head and the eastern wall opposite the river mouth exhibit a channelized seafloor, with gently meandering channels that merge downslope. Subbottom records show recent eolian gravitational faulting on the walls. On the upper canyon floor, extensive fields are present of what have been described in other settings as migrating sediment waves. These waves appear to be modified in places by internal slumping and interrupted downslope by unstratified (debris flow?) regions. Acoustically transparent units may represent mud-rich turbidites on the canyon floor. Together, these features suggest the canyon is regularly swept by gravity flows of river-derived sediment that are channelized in steeper wall areas and downslope may provide a mechanism for sediment wave migration. COOPER LIMITATION OF THE MARINE AMMONIA OXIDIZING ARCHAEOGEO- NITROSOPHILIALIUS MARITIMUS

Copper is a required and often limiting micronutrient for microorganisms in the ocean because of its role in electron transfer and redox reactions, including ammonia oxidation and denitrification. However, copper can also be toxic at high concentrations. Ammonia
oxidizing archaea (AOA) have recently been recognized as the primary nitrifiers in the marine environment, thus playing an important role in the nitrogen cycle. Available genome sequences of AOA show that Cu-dependent enzymes are essential for both ammonia oxidation and electron transfer in these organisms indicating a particularly high requirement for copper. However, our knowledge of the copper requirements of AOA and their contribution to copper species in the ocean is non-existent. Here, we report the copper requirements of the AOA Nitrosopumilus maritimus using a defined trace-metal buffered medium and show that the common chelator EDTA is inhibitory to growth and ammonia oxidation, an effect that appears to be due to direct inhibition rather than an indirect one via metal limitation. Instead, we use the strong copper chelator TETA to characterize copper limitation and toxicity and their underlying effects on ammonia oxidation in N. maritimus. In addition, we present preliminary evidence for the production of a strong copper binding ligand by N. maritimus. These results highlight the underlying importance of copper to the metabolism of AOA and the marine nitrogen cycle. (Abstract ID 12547)

TRACING DISSOLVED ORGANIC CARBON FROM THE ARCTIC WATERSHEDS TO THE ARCTIC OCEAN

The Arctic Ocean receives about 11% of the global carbon discharge from rivers that drain vast regions in the Arctic and Subarctic climatic zones. We have used lignin biomarkers and fluorescence to trace terrigenous organic matter (TOM) sources in 6 large Arctic rivers and Ocean. The Siberian rivers, Lena, Yenisei, and Ob contribute 90% of the mostly forest-derived DOM. During low flow, lignin biomarkers indicate a larger contribution from peat bogs, soils and mosses. Within the Arctic, the Eurasian Basin (EB) has higher levels of TOM relative to the Canada Basin (CB) and highest levels of TOM are found in the halocline. The relationship of fluorescence and lignin phenols is strong in the EB but weak in the CB. This has to do with additional fluorescence sources and vertical partitioning of TOM in the CB. Our results indicate that sea ice formation plays a prominent role for the vertical distribution of TOM along isopycnals. The observed distribution of lignin and fluorescence in surface waters raises important questions for the Arctic carbon and freshwater cycle. (Abstract ID 12467)

EFFECT OF GREENLAND ICE SHEET MELTING ON NORTH ATLANTIC CLIMATE VARIABILITY

Using a CGCM, we investigate the effect of the Greenland ice sheet melting on Arctic climate variability. The positive-degree-day (PDD) method was adopted to control the ice melting. The model with and without the PDD method produces rather realistic North Atlantic SST pattern on the decadal-to-multidecadal timescale, but the significant multidecadal variability is solely observed in PDD experiment. This quasi-oscillatory mode is attributed to two feedback processes: a leading density-driven positive feedback and a lagging wind-driven negative feedback. The reduced evaporation from the cold surface leads to the reduction of the density, and so the slowdown of AMOC, and the weakening of northward heat transport cools to cool North Atlantic. On the other hand, the surface low pressure over the north of the cold surface generates the northward warm advection though the Sverdrup adjustment, which reduces the cooling. Two feedback processes produce the interdecadal variation in North Atlantic. Finally, when the Greenland ice melting process is involved, the cold (warm) SST exerts to decrease (increase) the ice melting, which intensifies (reduces) the AMOC so does the warm (cold) advection. Therefore, the melting of ice sheet likely works as the negative feedback. So this negative feedback partly compensates the aforementioned density-driven positive feedback, which may result in the longer time scale fluctuation. (Abstract ID 9937)

TOWARD UNIFIED APPROACH TO REMOTE ESTIMATION OF CHLOROPHYLL CONCENTRATION IN COMPLEX COASTAL, ESTUARINE AND INLAND WATERS

We present here results supporting the use of NIR-red algorithms for remote estimating chlorophyll-a (chl-a) concentration in complex turbid productive waters. We tested the potential of universal applicability of NIR-red algorithms, which were calibrated using reflectance and in situ data from Nebraska Lakes and data that were synthetically generated using a radiative transfer model. We used an extensive set of field spectrometer data from the Chesapeake Bay and several lakes in Nebraska (USA), Lake Kinneret (Israel) as well as MERIS imagery and in situ data collected in the Azov Sea and the Taganrog Bay (Russia) to test the accuracy of the algorithms. We found that the NIR-red algorithms gave consistently highly accurate estimates of chl-a concentration. The algorithms do not need case-specific parameterization and presents a strong case for the use of the NIR-red algorithms for real-time quantitative monitoring of chl-a in an estuarine, coastal, and inland waters. IMPACT OF EXPERIENTIAL OCEAN SCIENCE EDUCATION ON SCIENTIST-VOLUNTEER KNOWLEDGE, TEACHING CAPACITIES AND NSF BROADER-IMPACTS Endeavors

Ocean Inquiry Project (OIP) — a strategic partner of COSEE-Ocean Learning Communities — connects ocean scientists and members of the public in deep and meaningful learning experiences, while doing rigorous, scientific data collection. OIP operates a boot-based education program to collect data and teach marine volunteers. K-12 and community college audiences about the Puget Sound ecosystem as well as about current ocean science research. In 2011 OIP sought to understand the impact of these experiences on the participating scientists. Since 1999 more than 70 scientists have served as volunteer instructors during day-long cruises on Puget Sound. The evaluation approach was to interview those who matched the criteria of serving during the COSEE-OIL era (2008 to present). The interviews focused primarily on how OIP experiences affected scientists’ teaching, scientific knowledge and NSF Broader Impacts endeavors. Key findings include that all scientists: 1) reported increased teaching confidence and skills with both formal and informal audiences, and 2) identified Broader Impacts as a critically important service to the public and a serious obligation for scientists, and 3) gained new scientific knowledge during the cruises. HOW DOES PARTICIPATION IN EDUCATIONAL OUTREACH BENEFIT SCIENTISTS?

For almost a decade, scientists and educators have been collaborating on several education and public outreach initiatives as part of the Center for Ocean Sciences Education Excellence (COSEE). While the goals and strategies of the COSEE are multi-faceted, during this session we will share results from research conducted to learn about the impact of these collaborations on scientists. Analysis of survey and interview data has revealed several possible direct benefits to scientists: (1) support for accessing research funding through help in developing broader impact and EPO (education and public outreach) statements; (2) opportunities for the scientists and their graduate students to engage in education and outreach; (3) personal fulfillment and enjoyment of engaging in education and outreach; (4) change in attitudes about teaching, learning, and the role that public understanding of science plays can play in society; (5) change in their own teaching practice; (6) change in thinking about their scientific pursuits, (7) increased demand and support for science research funding through public understanding; and (8) developing more institutional support for scientist participation in education and public outreach. ULTRA-VIOLET ABSORPTION SPECTRA: OPTICAL RETRIEVAL OF NITRATE CONCENTRATIONS IN HIGH CDOM WATERS

Understanding the role of nutrients in phytoplankton dynamics requires synoptic measurements of nutrient concentrations and phytoplankton biomass. The Satlantic ISUS nitrate sensor utilizes the ultraviolet absorption features of nitrate against a background of other dissolved species to estimate the nitrate concentration. This has worked well in open ocean settings away from temporally-varying high concentrations of colored dissolved organic matter (CDOM). Here we present an approach of deconstruction of the UV absorption spectrum into contributions by dissolved salts, terrestrially-derived organic matter and nitrate. A linear model is proposed that yields the concentrations of each component from simple spectrophotometric analyses. The model is tested in a dynamic coastal sound with strongly varying concentrations of salts, dissolved organic matter and nutrients. The sensitivity of the observations to the optical density of the samples in the ultraviolet is discussed. The utility of this approach is two-fold: (1) archival UV CDOM absorption spectra can be re-analyzed to retrieve nitrate concentrations and (2) tuning of the absorption reconstruction invoked by the Satlantic ISUS sensor can provide more robust estimates of nitrate in high CDOM coastal waters. NATURAL AND ANTHROPOGENIC ORGANIC CHEMICALS IN THE ZANZIBAR
Using these instruments, high vertical resolution (<10 cm) data in the near-surface layer were acquired nearly all the way to the sea surface, allowing for an examination of the near-surface structure and variability usually not possible in the context of Argo floats. To date, twenty-eight Argo-type floats equipped with STS units have been deployed in the Pacific, Atlantic, and Indian Oceans. The vertical variability of temperature and salinity in the near-surface layer are characterized for each of these regions. Additionally, comparisons of STS and primary sensor CTD data are presented. Results show the upper few meters of the ocean to be well-mixed at most times, interrupted by significant and often short-lived warming/cooling and freshening events. These results can be compared and contrasted to results from the sea surface obtained from orbiting platforms. (Abstract ID 10701)

ENSEMBLE DATA ASSIMILATION AND UNCERTAINTY QUANTIFICATION

Geophysical data assimilation algorithms combine a forecast from a model with observations of a physical system to get an improved estimate of the probability distribution of the system. Ensemble data assimilation algorithms are designed to produce a small sample of state estimates from this distribution. In the best of all possible worlds, estimates of uncertainty and sensitivity can be obtained directly from this sample. However, deficiencies in forecast models and the observing system coupled with limited computational resource lead to ensemble estimates that are far from optimal. An overview of ensemble algorithms is presented and possible problems with uncertainty estimates are discussed. Enhanced ensemble algorithms, for instance adaptive inflation of prior ensembles, that use observations to produce improved uncertainty estimates are discussed. (Abstract ID 11555)

YOU ARE WHERE AND WHAT YOU EAT – SYMPATHETIC COMPETITORS AND DIET MAY DETERMINE THE EFFECT OF PHYSICAL HABITAT ALTERATION ON MERCURY IN FRESHWATER FISH

Freshwater fish accumulate toxic methyl-mercury in their flesh from the prey they consume. Because methyl-mercury is not easily released it bioaccumulates through the aquatic food chain and can reach levels of concern for human and animal piscivores. Considerable attention has been paid to understanding the determinants of mercury levels in fish and to the consequences of anthropogenic perturbation. Lake and watershed characteristics are known to play a significant role however; they do not explain all the intervariability. Biological and ecological characteristics such as growth rate and foodchain length have also been shown to influence mercury accumulation. Here we use a large dataset from over 100 lakes in Labrador, Canada to demonstrate how the presence or absence of sympatric competitors affect mercury accumulation either through changes in habitat use (longnose suckers) and/or prey selection (round whitefish) while diet choices may explain variations observed in opportunistic predators (brook trout). Predicting mercury in fish following changes to physical habitat within aquatic systems will therefore depend on species autecology and community structure through their influence the prey selection and availability. AEROSOL SUPPLY OF SOLUBLE TRACE ELEMENTS TO THE OCEAN EVALUATED USING PAIRED THORIUM ISOTOPES

Aerosols (dust) supply dissolved 230Th to the ocean just as they serve as a source of micronutrients and other trace elements. Surface waters in regions downwind from major dust sources are enriched in dissolved 230Th, reflecting this source. The residence time of dissolved Th is evaluated by measuring the radioactive disequilibrium between dissolved 230Th and its parent, 234U. Assuming steady state, which is reasonable when dissolved 230Th inventories are integrated through the thermocline, the quotient of the dissolved 230Th inventory divided by the resulting time of dissolved Th provides the mean annual flux of dissolved Th from aerosols. Application of these principles will be illustrated using results from the NW Pacific, downwind...
of Asian dust sources, as well as results from the eastern tropical Atlantic, in a region of high Saharan aerosol flux. For the Atlantic, we will also show that surface concentrations of dissolved Th are positively correlated with concentrations of dissolved Al, a more traditional tracer of dust supply. LAGRANGIAN OBSERVATIONS OF ACCELERATION IN BREAKING WAVES
A complete understanding of wave generation, propagation and transformation is necessary to correctly model nearshore processes. Among the most difficult problems is understanding the dynamics of breaking waves. In this presentation we will present preliminary results from synoptic observations of particle accelerations using a novel strategy that involves the development of new Lagrangian drifters equipped with sensors that can be deployed within breaking waves. The drifters measure particle acceleration and rotation with miniature inertial measurement units in an effort to reconstruct the 3D distribution of turbulence in spilling development of new Lagrangian drifters equipped with sensors that can be deployed within breaking waves using Lagrangian drifters. (Abstract ID 10728)

TOWARDS THE ATTRIBUTION OF RECENT TRENDS IN OCEANIC OXYGEN TO CLIMATE CHANGE AND VARIABILITY
Oceanic oxygen distribution responds to climate forcing, such that observed historical declines in O2 concentration across nearly all ocean basins are likely related to global ocean warming. Any long-term trends in O2 are, however, superimposed upon significant interannual to decadal variability relating to the dominant climate modes, which can act to mask any anthropogenic signal. Our study aims to better quantify the relative contribution of natural and anthropogenic forcing to observed oxygen changes. For this purpose, we used an ocean biogeochemistry model (PlankTOMS-NEMO) forced with a suite of atmospheric fields derived from reanalysis products and the CMIP5 model archive. We isolate the internal variability in marine oxygen from the long-term trends driven by climate change using targeted experiments. We compare our modelled oxygen changes with observations to determine whether natural variability or anthropogenic climate change as produced in the models can explain observed widespread decreases in sub-surface O2 between 1970 and 1990, and the long-term (50 year) declines in dissolved oxygen concentration of the tropical thermocline. PARAMETERIZATION OF THE DARDALENES OUTFLOW IN THE AEGEAN SEA FROM THE BLACK SEA WATER BUDGET
The Black Sea Waters (BSW) outflow through the Dardanelles Straits is the strongest buoyant input for the Aegean Sea and determines significantly the hydrodynamic and physical characteristics of this region, with implications in the Eastern Mediterranean water masses. A new mathematical scheme is adapted to parameterize the large buoyant Dardanelles outflow that is not routinely monitored through the water budget of the adjacent Black Sea, which is available from atmospheric operational models. The scheme was applied in the 3-d hydrodynamic N. Aegean Sea HYCOM model (NAS-HYCOM, 1.5x106 cells). Validation of the parameterization approach showed higher correlation between model results and satellite and in situ data, in comparison to previous parameterizations that employed targeted experiments. We compare our modelled oxygen changes with observations to determine whether natural variability or anthropogenic climate change as produced in the models can explain observed widespread decreases in sub-surface O2 between 1970 and 1990, and the long-term (50 year) declines in dissolved oxygen concentration of the tropical thermocline. RECONSTRUCTING ESTUARINE PALEOCLIMATE FROM MIDDEN SAMPLES: CHALLENGES OF TRANSPORTATION ACROSS SALINITY GRADIENTS.
Archaeological shell middens are increasingly utilized as sample sources for sclerochronological oxygen isotope paleoclimate reconstructions. Most middens are dominated by estuarine shell taxa. As such, uncontrolled and variable δ18O data profiles from the mid-Holocene Sapelo Island Shell Ring complex, 18Owater values confound interpretation of whether natural variability or anthropogenic climate change as produced in the models can explain observed widespread decreases in sub-surface O2 between 1970 and 1990, and the long-term (50 year) declines in dissolved oxygen concentration of the tropical thermocline. (Abstract ID 10367)
by site inhabitants may obscure underlying climate signals. This illustrates one factor that differentiates middens from non-anthropogenic sources of sclerochronology samples. The impact of transportation of shells from different habitats will be explored both in terms of how it contributes to incorrect interpretations of climate change and how such problems can be avoided. INFLUENCE OF OCEAN COLOR DATA REPROCESSINGS ON SATELLITE-DERIVED CHLOROPHYLL CONCENTRATIONS IN THE PATAGONIA ARGENTINIAN SEA

A complete reprocessing of the entire satellite ocean color images is performed by OBPG-NASA when significant changes are made in algorithms, in processing schemes, etc. OBPG-NASA also performs a global scale validation and comparison of ocean color products after every reprocessing. In this work, we compared three distinct datasets: in situ, SeaWiFS and MODIS/Aqua satellite-derived chlorophyll data in the Patagonia Argentinean Sea, for two successive reprocessing (R2007 and R2009). Reports based on R2007 have pointed that SeaWiFS satellite data tends to overestimate chlorophyll concentration in zones of high pigment concentration in global scale. In R2007, the differences between SeaWiFS and MODIS/Aqua chlorophyll were dependent on concentration, with higher SeaWiFS/MODIS/Aqua values at low (high) pigment concentrations in Patagonian waters. Validation based on R2009, showed that SeaWiFS and MODIS/Aqua sensors underestimated in situ chlorophyll for concentrations above 1 mg m⁻³. Moreover, in R2009, the satellite-derived differences were independent on concentration, with higher MODIS/Aqua than SeaWiFS chlorophyll values. Therefore, changes in the differences between satellite/satellite and satellite/in situ chlorophyll concentrations caused by different reprocessing have also to be assessed at regional scales. SEPARATING WHITECAP FRACTION OF ACTIVE WAVE BREAKING FROM SATELLITE ESTIMATES OF TOTAL WHITECAP FRACTION

As a surface expression of breaking waves, the oceanic whitecaps are manifestation of various air-sea interaction processes. Whitecap fraction observed from satellites-borne microwave radiometers provide the total whitecap fraction W, including foam generated during active wave breaking and residual foam left behind by these breaking waves. The total fraction is important for predictions of sea spray aerosol production and heat exchange. However, the active portion WA, is necessary for evaluating processes such as turbulent mixing, gas exchange, ocean ambient noise, and spray-mediated intensification of tropical storms. It is thus highly pertinent to be able to separate WA from W. Phillips concept of breaking wave statistics connects WA with the energy dissipation rate of breaking waves. We can estimate WA by combining the Phillips concept with dissipation rate values obtained from buoy measurements of the wave spectra. We will present the principle of separating WA from W; and preliminary results from one year buoy data matched in time and space with satellite observations of W. (Abstract ID 11665)

VORTICAL MODE STIRRING, INTERNAL WAVES, AND THE INVERSE ENERGY CASCADE

Patches of well mixed fluid are spacial and ubiquitous in the ocean. The geostrophic adjustment of many mixed patches leads to vortical mode-stirring and is thought to enhance lateral dispersion. If vortical modes are densely populated, they interact, and an inverse energy cascade can occur. Numerical experiments were performed to study the effect of a large-scale internal wave on vortical mode fields and the associated inverse energy cascade. The internal wave shear does not disrupt the inverse cascade. Rather an internal wave can excite an inverse energy cascade by enhancing vortex interaction. Development of the instability of the vortices is quickened by the wave shear, and vortices split into propagating dipoles. If vortical modes are so densely populated that they interact even without the presence of a wave, adding a background wave enhances the inverse cascade. Continuous forcing of vortical modes and internal waves is necessary to maintain the inverse cascade. (Abstract ID 11738)

GEOREGIONAL DISTRIBUTION OF DIURNAL AND SEMI-DIURNAL PARAMETRIC SUBHARMONIC INSTABILITY IN A GLOBAL OCEAN CIRCULATION MODEL

Simulations from a global ocean circulation model forced by atmospheric forcing fields and both semi-diurnal and diurnal astronomical tidal potential are used to investigate the presence of parametric subharmonic instability (PSI) arising from both diurnal and semi-diurnal tides. A previous investigation observed PSI in a global model due to the M₂ internal tide (Simmons, 2008). The model used in that case did not include atmospheric forcing, PSI was found in narrow regions around the critical latitude (CL) of the M₂ subharmonic (latitude ± 28.8 degrees). The atmospheric forcing included in the simulations presented here leads to horizontally varying stratification, and vigorous mesoscale and near-inertial fields. In the case of the semi-diurnal tides, evidence of PSI is found around the CL but occupying a broader range than previously observed. The PSI arising from the diurnal tides have, for the most part, comparable variances equatorward of their maximum critical latitude (± 14.5 degrees) and are not as localized around these latitudes. BIOLGICAL AND ECO SYSTEM OBSERVATION OF THE DEEP OCEAN

The deep oceans are becoming an increasingly important source of food, energy, minerals, and genetic resources; but we still lack scientific concepts and societal regulations as to their sustainable use and protection. One reason for the large uncertainty as to human impact and the time scale and effect of global change on deep-water ecosystems is the lack of spatial and temporal studies with comprehensive approaches. There are only few deep-sea areas worldwide where time series and integrated ecosystem data exist, to define a baseline against which natural variation and human impact could be assessed. Hence, deep ocean observations merit renewed attention in the context of recent technological advances in underwater imaging, acoustics, in situ sensors and chemical analyzers. The range of autonomous, continuous measurements for assessing derived variables such as ecosystem function, biodiversity and biogeochemical processes are still a major technological challenge, often limiting the assessment of variation in deep water ecosystems to a few physical parameters. This presentation discusses the need for integrated ocean observation and new concepts enabling ecosystem assessment in the deep ocean. Examples are given from regional annual to decadal seafloor observatories in temperate and polar seas. (Abstract ID 12628)

EUROPEAN PROSPECTS FOR A GEOSTATIONARY OCEAN COLOR SENSOR: THE “OCEAN COLOR ADVANCED PERMANENT IMAGER” (OCAPI)

The “Ocean Color Advanced Permanent Imager” (OCAPI) mission aims at hourly observations of ocean color in coastal zones and the open ocean from a geosynchronous (GEO) orbit, at a nadir resolution of 250m over the entire Earth’s oceanic and coastal areas as seen from a GEO position over Europe. This includes virtually the whole Atlantic Ocean, the Mediterranean Sea and European Nordic seas. The science domains that would benefit from a global GEO ocean color observation from a geostationary satellite over Europe. This includes virtually the whole Atlantic Ocean, the Mediterranean Sea and European Nordic seas. The science domains that would benefit from a global GEO ocean color observation are: ocean color biology and physics and biology and the consequences on primary production and carbon fluxes, the assimilation of coupled ocean physical-ecosystem models, the study of the dynamics of the coastal ocean ecosystems, the quantification of sediment and carbon transport and fluxes from land to ocean, the study of aerosol transport from land to sea, including dust or volcanic aerosols. We will present the preparatory scientific activities that underlay this mission proposal, as well as the status of definition studies for the mission and instrument concepts. (Abstract ID 11112)
The accident of the Fukushima Daiichi Nuclear Power Plant (TEPCO, Japan) caused radionuclide release in marine environment. Although total amount of radionuclide that has entered the ocean is unknown, the radionuclide, i.e. 131I, Cs-134, Ag-110m etc., was not detected before this accident, was detected in deposition, seawater, sediment and marine organisms. To investigate the long-term behaviour of radionuclide in the marine environment, several marine samples, i.e. seawater, sediments, biological samples were collected in the seas around Fukushima and their radionuclide activities were measured. The Cs-134 and Cs-137 activities in surface seawater off Fukushima on August were ranged from 0.02 to 0.2 Bq/L, respectively, and the Cs-134/Cs-137 activity ratios were almost 0.9. We will discuss the variation of radionuclide activities in marine samples to assess these effects in marine environment. (Abstract ID 11248)

CREATING CONCEPTUAL DIAGRAMS WITH ADOBE ILLUSTRATOR: AN IMPORTANT COMMUNICATION TOOL FOR PRE-CAREER SCIENTISTS

Conceptual diagrams are a versatile tool for communicating scientific information in a straightforward and informative manner and are, as such, a valuable approach to increasing ocean literacy among non-scientist and informal audiences. Using Adobe Illustrator, we have developed an extensive symbol library that can be used to create conceptual diagrams that strengthen understanding of marine ecological processes. For educators, the interactive process of creating conceptual diagrams with learners improves their understanding of ocean science, as well as reveals prior knowledge and misconceptions, and is thus well-suited for a constructivist approach to concept development. For pre-career scientists, conceptual diagrams help simplify and visualize understanding of one’s own research and provide a valuable medium for communicating science in an accessible manner to a broad range of audiences. Our presentation will provide an overview of how to incorporate conceptual diagrams into COSIA courses and other pre-career scientist training. We will also provide concrete examples of how conceptual diagrams have been implemented as a learning and communication tool, specifically through modules created in collaboration with CONSE Coastal Trends. EARLY DETECTION OF THE INVASIVE ASCIDIANS BOTRYLLUS SCHLOSSERI AND BOTRYLLOIDES VIOLEAUS UTILIZING TAQMAN ASSAYS

The ascuculture industry on the Atlantic and Pacific coasts of Canada is being threatened by the invasion of non-indigenous species. Two species that are particularly problematic for mussel aquaculture are the ascidians Botryllus schlosseri (SCH) and Botrylloides violaceus (VIO). Without early detection mitigation has been ineffective. The biggest challenge for early detection is that the eggs and larvae of many ascidian species are morphologically similar, making visual identification difficult. Thus, genetic techniques for identification are being developed. To date, partial sequences for the cytochrom c oxidase 1 (COI) gene of multiple individuals representing multiple colour morphs for VIO have been sequenced. COI sequence alignments have been performed to identify areas that are conserved intraspecifically but not interspecifically. From the intraspecifically conserved sequences, species-specific TaqMan real-time polymerase chain reaction assays were designed and tested. We aim to develop TaqMan assays that may be used to identify the presence of VIO and SCH larvae and fragments globally. The sequence data will also be used to gain insight into possible source populations of these ascidians in Newfoundland. (Abstract ID 10571)

IMPACT OF INTERNAL TIDES ON THE WAVENUMBER SPECTRUM OF SEA SURFACE HEIGHT

The slope of the wavenumber spectrum of sea surface height (SSH) is used to infer the dynamics. Internal tides are ubiquitous high-frequency motions in the ocean, which can mask the variability from other types of motions. We utilize a new global simulation, which simultaneously contains both atmospheric and tidal forcing, to determine the impact of internal tides on the SSH wavenumber spectrum. We examine the spectra in regions of strong and weak internal tide in both 1/12 and 1/25 degree global simulations, and in 1 km regional simulations. With the hourly output all SSH can be separated into high- and low-frequencies. In regions near Hawaii the slope of the wavenumber spectrum of the low-frequency sea surface height lies near the predictions of surface quasi-geostrophic theory, but is buried underneath the much larger internal tide signal. The implication for the planned wide-swath satellite altimeter mission is that in regions of high internal tide activity the tidal corrections on meso- and submesoscales will need to be very accurate for non-tidal dynamics to be revealed. HUMBOLDT SQUID STATLITH MICROCHEMISTRY STUDY USING LASER ABLATION INDULECTIVELY COUPLED PLASMA MASS SPECTROMETRY (LA-ICP-MS)

The Humboldt Squid, Dosidicus gigas, is expanding its historical habitat range of the Eastern Equatorial Pacific both north and south. It has been sighted in Alaska and may have an established population in Monterey Bay, California. Although there is concern for fisheries species being decimated by this new predator, there is much about the population structure of Humboldt squid that is not well understood. In order to learn more about the life history and population dynamics of this species, we researched the microchemistry of small calcium carbonate deposits known as statoliths. Sample specimens were collected from three geographic regions. Statoliths are deposited in daily layers of aragonite and incorporate trace elements reflecting the individual squid’s behavior. We will present variations in microchemistry comparing the geographic groups as well as changes during the life of individuals as determined using LA-ICP-MS. Patterns in microchemistry may occur as the animals grow, mature, and migrate. Differences between populations may show how the sample groups utilize opportunistic strategies to survive in different geographic regions and will contribute to understanding the life history of this species. APPLICATION OF HIGH FREQUENCY (HF) RADAR AND THE OKUBO-WEISS PARAMETER TO ANALYZE SUBMESOSCALE VARIABILITY IN THE FLORIDA CURRENT

The Florida Current (FC) is a coastal oceanic regime with large horizontal shears, local vorticity maxima and topographic constraints. Small-scale vortices are generated on its western flank that travel northward along the continental shelf offshore of South Florida. Transient submesoscale features with scales of a few kilometers are not easily observed by traditional in-situ instruments or satellites, but are well resolved by HF radar. Dual-station HF Wellen Radar (WERA), operating at 16045 MHz, acquired a nearly continuous data set of surface current velocities at 20-min intervals with a range of 80 km, and a horizontal resolution of 1.2 km over the past several years. These data are quality controlled and objectively mapped to a uniform grid 45×45 km (1980 cells). The Okubo-Weiss (OW) parameter is estimated to connect regions of positive vorticity that represent cyclonic submesoscale events. The relative contributions of the OW terms (stress, data are quality controlled and objectively mapped to a uniform grid 45×45 km (1980 cells). The Okubo-Weiss (OW) parameter is estimated to connect regions of positive vorticity that represent cyclonic submesoscale events. The relative contributions of the OW terms (stress, strain, vorticity) are isolated to examine their behaviour on the observed current structure. We attempt to relate events to wind stress, FC-variability, and topography to understand the dominant forcing mechanisms. (Abstract ID 12568)

DATA QUALITY IMPROVEMENTS FOR SATELLITE SEA SURFACE SALINITY DATA

The recently available SMOS sea surface salinity (SSS) exhibits areas of increased measurement error (associated with land contamination, RFI, auxiliary wind product deficiencies, external noise or instrument inaccuracies). In this study, we present some of the strategies developed at the SMOS-BEC to improve SSS data quality. Ocean Target Transformation (OTT) is used in the operational Level 2 processor. Three conflicting factors impact its efficiency: the number of observations used to compute the OTT (more data increase robustness); 2) the apparent instrument (temporal) drift (requiring periodic OTT updates); and 3) the effect of latitudinal variation (suggesting the need for spatial OTT filtering). We propose several palliative procedures for OTT deficiency mitigation. Additionally, we present an updated sea surface roughness formulation based on retrieved SMOS data. The dependencies with incidence angle and several roughness-related parameters (wind speed, mean square slope, significant wave height, wave age, wind stress) are considered in the improved approach. We also introduce a method for optimal multi-regime estimation of missing data (zones of too large error). First, by combining data from moored stations (TAO/TRITON) with model results (ECCO-JPL) treated as synthetic data, we achieve improved quality predictions. Then, the method is used to fill areas that have been flagged as having too large errors while preserving the non-Gaussian character of the SSS data. (Abstract ID 11954)

MECHANISMS CONTROLLING STRATIFICATION AT TIDAL TIME SCALES IN DELAWARE BAY ESTUARY

Observations in the Delaware River estuary revealed that tidal period variability in salinity stratification is inconsistent with the classic model of tidal straining (Simpson et al., 1990). In particular, we consistently observed stronger stratification during the flood relative to the ebb. Qualitatively the tidal period variability is the result of lateral flows acting on the cross-channel salinity gradients that tend to stratify the water column during flood while their reversal on ebb reduce stratification. However the spatiotemporal structure of the lateral flows are complex and suggestive of Ekman processes that are modified by tidal period lateral baroclinic adjustments. We diagnosed the rate of change of potential energy to quantify the importance of the lateral flows relative to the along channel flows in driving tidal period variability in stratification. Results demonstrate that lateral flows in fact compete against the along channel flows and point to the important roles of mixing and frontal systems in modifying the tidal period variability in potential energy. (Abstract ID 11958)
underway data to NOCDC; 2) a procedure for “first-pass” rapid assessment of data quality that yields a set of summary statistics and data plots after each cruise; and 3) coordinated links between the R2R cruise catalog, original data archived at NOCDC, and processed products at JASADCPR. We will present initial results and lessons learned. (Abstract ID 11529)

THE INFLUENCE OF PHYTOPLANKTON COMMUNITY STRUCTURE ON NET COMMUNITY PRODUCTION AND AIR-SEA CO2 FLUX IN THE SUBTROPICAL AND SUBARCTIC NORTH PACIFIC

We used continuous underway measurements of the ratio of dissolved oxygen to argon gas (O2/Ar) and SeaFlow (a novel underway flow cytometer) in the surface mixed layer to estimate net community production rates (NCP) and phytoplankton community structure at ~4 km resolution across the subtropical and subarctic north Pacific during container ship cruises from Hong Kong to Long Beach in May and July 2011. Phytoplankton populations were classified based on size, pigment composition. We observed a range in O2/Ar saturation from a mean 0.1 (± 0.4)% in the subtopics to 18% in a frontal region off the coast of Japan, which corresponded to a NCP range of 1.7 (± 2.5) to 200 mmol O2m2d-1. Increased NCP in this frontal region was highly spatially correlated with increased surface chlorophyll-a and particulate organic carbon concentrations and shifts in the phytoplankton community from Synechococcus to ultraplankton dominated regions. Additionally, estimates of air-sea CO2 flux, gross oxygen production rates (from isopotes of dissolved oxygen), and the export ratio will be presented. (Abstract ID 10713)

COMPARISONS OF REGIONAL SEA SURFACE TEMPERATURE GRADIENTS FROM MODIS AND AVHRR

Investigations of sea surface temperature (SST) gradients are becoming more prevalent especially in interdisciplinary applications such as fisheries and ecological habitat characterizations. SST fronts are also often correlated with ocean properties such as water mass, and biological variables such as chlorophyll and nutrients, and therefore are used to characterize and predict habitat. In this study regional SST gradients and fronts are examined for a six year time series comparison using data from MODIS on Aqua and AVHRR. Two regions, one in the California Current System and the other in the Gulf Stream, representing an eastern boundary upwelling region and strong western boundary current, respectively, were chosen to investigate the seasonal variability, statistical differences and similarities, and correlations with respect to the two sets of SST gradients. Results indicate higher gradient magnitudes for the MODIS SST gradients relative to those derived from AVHRR that are attributed to instrument and algorithm differences. These observed differences are important for any studies that employ SST gradients, such as fisheries investigations that have traditionally relied on AVHRR SST gradients only. (Abstract ID 10857)

GENERALIZED OPTIMALITY SOLUTIONS FOR NUTRIENT TRADEOFFS IN PHOTOACCLIMATION AND PHOTOSYNTHESIS IN GEIDER ET AL. (1998)-TYPE MODELS

The Geider et al. (1998) model of photoacclimation, photosynthesis, and nutrient limitation is based on an exponential functional form for the photosynthesis-light relationship. Armstrong (2006) used this exponential form in proposing an alternative photoacclimation/ nutrient limitation model based on optimality. Here I generalize the optimality approach to any “reasonable” functional form, and present a set of algebraic models with more tractable mathematical properties. Unlike the exponential, the two simplest algebraic forms can be integrated over depth intervals, making their use in earth system models efficient computationally. Simultaneous fits of chlorophyll/carbon ratios, nitorgen/carbon ratios, and growth rates to this set of algebraic models, as well as to the exponential model, has allowed identification of problems in calibrating photosynthesis models; the most serious of these is that inappropriate use of data from nutrient-sufficient cultures can lead to unstable parameter estimates. These insights could not have been obtained had only a single model been subject to calibration. (Abstract ID 11757)

MIXING IN FJORDS AND THE RELATION BETWEEN LOCAL ENERGY DISSIPATION AT A FJORD SILL AND RADIATED INTERNAL TIDES

Diapycnal mixing in a sill fjord is vital for renewal of the deep water inside the sill. Tides can cause such mixing, both by local turbulence at the sill associated with supercritical baroclinic flow and internal hydraulic jumps, and by radiation of internal tides away from the sill that dissipate elsewhere and cause turbulence and mixing there. Previous studies tend to look at these two processes as independent of each others, whereas they in reality are closely linked: The internal tide generation depends on the hydraulic conditions at the fjord sill, and the internal hydraulic jump strength depends on the upstream and downstream radiated columnar disturbances which over time constitute the internal tides. An effort is done to link the hydraulic theory and the internal tide generation theory, and the result is compared to recent intensive observations over the Oslo fjord sill, including high-resolution microstructure profiler transsects and mooring data on and inside the sill. MONITORING OCEAN WATER LEAVING RADIANCE FOR INTER - SATELLITE CONTINUITY

A new approach is presented to track stability of ocean color products in global ocean waters. Time series of water leaving radiance (nLw) from different water types is used to track satellite ocean color which is used to derive ocean products. Various AERONET ocean color (AOC) sites and additional stable “blue” water regions provide a monitoring network to track the uncertainty of nLw from MODIS, MERIS, VIIRS, and GOCE. We determined, 1) regional “bias” of nLw in different ocean types and 2) inter-satellite “bias” that occur at these locations. We monitored “bias” by using a vicarious approach which propagates nLw to Top of Atmosphere (TOA) and determined the ratio i.e. “offset” from observed satellite TOA. We also introduce the creation of “synthetic AERONET –OC sites” based on MODIS nLw which are used with the vicarious approach for monitoring inter – satellite “bias.” Through monitoring yearly “bias” of sites in blue waters, we track the trends of inter satellite offsets of nLw and product validation. Results from coastal regions AOC suggest higher “bias” in nLw validation for several satellites. Decreased blue “bias” is observed in open ocean blue water regions. (Abstract ID 12162)

COMPARISON OF INTRATIDAL VARIATIONS OF SHEAR PRODUCTION, TURBULENCE DISSIPATION, AND MIXING ACROSS AN ESTUARY

Measurements were obtained in the James River estuary to compare intratidal variations of shear production, TKE dissipation, Reynolds stresses and vertical eddy viscosity values at two locations across a transect. Experiments were carried out for four semidiurnal tidal cycles during May 2010 (two in neap, two in spring) with the purpose of investigating channel to channel slope variations of these parameters during a spring/neap modulation. Two bottom-mounted 1 kHz ADCPs sampled velocity profiles in bursts, while a microstructure profiler (SCAMP) collected profiles of temperature gradient and electrical conductivity. The TKE dissipation was estimated via Batchelor fitting and compared to shear production, calculated using a structure function. During all surveys, the TKE dissipation showed intratidal variability that ranged from 10⁻¹⁰ to 10⁻⁵ m²/s³. The largest values were observed near bottom, with maximum (10⁻⁴ m²/s) values varying a different times in the tidal cycle, depending on the location across the transect. These observations will be compared to values Reynolds stresses and vertical eddy viscosity values (via Reynolds stresses and Osborn’s parameterization). (Abstract ID 11444)

INVESTIGATION OF A STRATIFIED BAROTROPIC MIXING LAYER WITH COORDINATE SYSTEM ROTATION

Submesoscale ocean dynamics are characterized by stable stratification and significant, but far from dominant rotational effects. We focus our study on a barotropic mixing layer having Rossby and Froude numbers initially of O(1). Both linear stability analysis (LSA) and direct
numerical simulations (DNS) are performed to analyze the model problem. LSA results suggest that strong stratification ($Fr < 1$) tends to stabilize the inertial instability, while increasing the range of vertical wavenumbers associated with barotropic instability. A new LSA result is that, when absolute vorticity is nearly zero at the inflection point, the range of vertical wavenumbers associated with barotropic instability greatly increases. Correspondingly, DNS of the nonlinear evolution show significant destabilization of the anticyclonic mixing layer including a rapid increase of the vortex stretching term when the flow transitions through the zero absolute vorticity state. A network of coherent longitudinal vortices emerges in the anticyclonic cases, while coherent vorticity evolves very similarly between the non-rotating and cyclonic cases. In the anticyclonic cases, breakdown into small-scale turbulence and secondary instabilities in localized regions of intensified vertical shear are also observed. (Abstract ID 11994)

TIDES UNDER THE ROSS ICE SHELF FRONT: CONTRIBUTIONS TO MIXING AND MELTING

Tides under the Ross Ice Shelf (RIS) contribute to mixing near the ice-shelf base, leading to basal melting and mass loss. Recent measurements of RIS basal melt rate indicate that rates are highest near the ice front, where tidal current characteristics change over short spatial scales. We use data from two moorings (M-1 and M-2) under the RIS near the ice front, and numerical model output, to investigate how tides might contribute to near-ice-front melting. The moorings measured water velocity, conductivity, and temperature for 2 months during the 2010 austral summer. Tidal analysis of the data revealed that ~50% of the current variability is caused by tides, particularly by the diurnal K1, O1, and P1 constituents. The CATS2008 Antarctic barotropic tide model results agree with our mooring analyses, allowing us to use this model to investigate tidal current variability elsewhere along the ice front. We also compare our measurements with the output from baroclinic models of the Ross Sea. These show seasonal variability of basal melt rates near the ice front, indicating the need for longer-term records of sub-ice-shelf currents. (Abstract ID 10699)

LOOKING UNDER THE ROSS ICE SHELF: TIDAL AND SUBTIDAL VARIABILITY

Two moorings (M-1 and M-2) measured water velocity, conductivity, and temperature under the Ross Ice Shelf (RIS) during the 2010 austral summer. Tidal harmonic analysis of the data revealed that ~50% of the current variability is caused by tides, particularly by the diurnal K1, O1, and P1 constituents. The tidal signal is consistent between the two moorings, with most of the tidal currents oriented roughly normal to the ice edge. The tidal energy flux computed with the mooring data shows a K1 energy transport into the RIS cavity and a smaller M2 energy transport out of it. The CATS2008 tidal model results agree with our calculations and suggest that the M2 constituent propagates like a Kelvin wave around the RIS cavity while the K1 behavior is more complex. Subtidal current velocities are incoherent between the two moorings but vertically coherent at each mooring. Progressive vector diagrams and nearby sea ice motion suggest that the M2 constituent propagates like a Kelvin wave around the RIS cavity while the K1 behavior is more complex. Subtidal current velocities are incoherent between the two moorings but vertically coherent at each mooring. Salinity gradients in the top few meters of the ocean surface can exist due to precipitation or other freshwater inputs. If present, they will complicate comparing salinity measured at depths of five meters typical of the ARGO drifters to salinities retrieved using L-band microwave radiometers, whose measurement depths are on order of 0.1 m. Therefore, understanding the spatial scales and temporal persistence of these gradients and the conditions under which they form will be important in understanding sea-surface salinity maps provided by Aquarius. Near-surface salinity gradients were measured by installing thermalalinographs (TSGs) in through-hull ports at depths of 2 m and 3 m on the R/V Thomas G. Thompson. Salinity gradients in the top two meters were also measured using a towed profiler that was capable of resolving gradients on the same vertical scale as the radiometric measurement depth. The results suggest that not only can precipitation produce gradients in near-surface salinity with horizontal spatial scales comparable to the footprint of Aquarius, the magnitude of the gradient is significant in terms of the overall accuracy of the satellite. DETECTING INTERANNUAL CHANGES IN PHENOLOGY WITH REMOTELY SENSED DATA: A COMPARISON OF THREE METHODS

Prior studies of the phenomenology of remotely sensed time series have applied different measures of phenological change and little effort has been made to compare approaches. I employed three new or revised methods to detect interannual fluctuations in phenological events in the California Current Ecosystem. The start, midpoint, and end of seasons characterized by either elevated SST, upwelling, or chlorophyll were identified based on 1) the date when a variable exceeded 75% of its annual range; 2) inflections of piece-wise curves fit to a time series; or 3) a non-stationary harmonic model. Events identified with the threshold and curve-fitting methods were closely correlated, whereas significant correlations were rare when comparing the curve-fitting and harmonic approaches. The low standard deviation of events identified with the harmonic method indicated this approach could not fully detect interannual variability. The other methods better characterized interannual variations, but had less power to distinguish seasonal signals from high-frequency fluctuations. Greatest consistency between methods was achieved when examining season midpoints. Future work should be sensitive to choice of phenomenological grid given each methods inherent benefits and deficiencies. (Abstract ID 10016)

A WINTER EXPEDITION TO EXPLORE THE BIOLOGICAL AND PHYSICAL CONDITIONS OF THE BERING, CHUKCHI, AND SOUTHERN BEAUFORT SEAS

Our understanding of seasonality, particularly winter conditions, in the Arctic is severely limited. This lack of knowledge has compromised our ability to model and to predict Arctic ecosystems, knowledge critical to our efforts to understand the potential impacts of ongoing climate change. In November-December 2011 we will be conducting a cruise on the USCGC Healy to the to the Bering, Chukchi, and Beaufort Seas. We have identified a set of key transects in the various cross-shelf-slope regimes along which we will conduct physical (hydrography, circulation), chemical (nutrients, dissolved organic matter), and biological (zooplankton, microzooplankton, chlorophyll, marine bird) sampling. Our objectives include describing hydrography, circulation, and aspects of the planktonic, nutrient, and dissolved organic matter environments, identifying the overwintering habitat of Calanus spp. and overwintering strategies of phytoplankton, determining the condition and activity (respiration) of Calanus spp., euphausiids, bacteria, and phytoplankton, and quantifying the coarse- and fine-scale vertical distributions of plankton and particles in relation to the vertical structure of the water column. Here we present preliminary findings on the hydrography and aspects of the biology from the winter cruise. (Abstract ID 9949)

MIXED LAYER HEAT BUDGET IN THE EAST CHINA SEA

In contrast to the effect of SST on the short timescale meteorological disturbances such as mesoscale cyclones, the climatological role of the SST distribution in the East China Sea (ECS) remains unclear. The atmospheric and oceanic reanalysis data indicate the northward migration of the climatological atmospheric front in the ECS is influenced by the ocean mixed layer temperature (OMLT) during early summer, suggesting an active role of ocean in a seasonal timescale. In order to clarify the mechanism responsible for the seasonal evolution
A season of glider missions in the western arm of Lake Superior revealed a wide variety of previously unobserved fine spatial and temporal structure in both physical and biogeochemical properties. These are the first observations made by an underwater glider in a large lake. Glider flights were made repeatedly along a 22 km long cross-lake section, measuring temperature, conductivity, Oxy-Cl fluorescence, backscatter, and dissolved oxygen throughout the water column. The flights revealed fine lateral spatial structure concentrated on the south shore of the section, which receives sediment-rich river input from Northern Wisconsin and the St. Louis Estuary, whereas less variability is found in the northern portion of the section, primarily fed by small rivers along the mostly bedrock north shore of Minnesota. Chlorophyll fluorescence shows a distinct subsurface maximum with coherence over tens of kilometers, and there are frequently multiple subsurface maxima, suggesting strong physical control of their formation or multiple phytoplankton populations with different light and temperature niches. CDOM distribution appears to be associated with river plume activity and unrelated to Chl-a distribution. (Abstract ID 11549)

THE IMPORTANCE OF GEOSTROPHIC ADVECTION IN REGULATING THE NORTH PACIFIC CARBON SINK

A broad swath across the North Pacific basin uptakes a disproportionately large amount of atmospheric CO2 every year, with the region of most intense uptake located in the North Pacific transition zone, from ~30°N to 40-45°N. In this work we use observational carbon data to investigate processes regulating air-sea CO2 flux in this region on seasonal and annual timescales by quantifying the impacts of temperature, biology; and physical circulation on seawater pCO2. We find that temperature effects dominate the pCO2 signal seasonally, yet support only 15-20% of the annual CO2 uptake in the region, via their impact on the solubility of CO2 in seawater. Instead, processes removing carbon from surface waters dominantly support the region's uptake of CO2 on annual timescales: the vertical export of organic carbon to depth, and the geostrophic advection of dissolved inorganic carbon laterally out of the region. We find the location of this carbon sink region, often attributed to a combination of biological and temperature effects, to instead be driven by the steady geostrophic divergence of DIC at these latitudes. COASTAL OCEAN RESPONSE TO WINTER STORMS IN THE BAY OF BISCAY (NORTH EAST ATLANTIC): IMPACT OF ATMOSPHERIC FORCING UNCERTAINTIES

This study presents the results of modeling experiments aiming at better understanding the response of the ocean surface layers to extra-tropical winter storms in the Bay of Biscay. What are the impacts of a strong winds event on surface currents, surface temperature and mixed-layer depth? How sensitive is this response to uncertainties in the atmospheric forcing? In particular, our objective is to characterize the effect of wind forcing uncertainties on the vertical mixing processes and advection terms that drive the mixed-layer temperature variability. We focus on the Bay of Biscay during the winter 2007-08. The circulation there is characterized by a high frequency variability due to the atmospheric variability, large barotropic and internal tides and slope current instabilities. We use the coastal regional model Symphone, developed at POC/ Laboratoire d'Aérologie (Toulouse, France). The model sensitivity to atmospheric uncertainties is analyzed from a stochastic modeling approach where an ensemble of simulations is generated by perturbing the wind velocity. Different regimes in the shelf and deep ocean are found, with large sensitivities of the sea surface temperature on the shelf. (Abstract ID 11027)

GLIDER OBSERVATIONS OF PHYSICAL AND BIOGEOCHEMICAL PROPERTY DISTRIBUTIONS IN LAKE SUPERIOR

of the OMLT, the heat budget is evaluated using the high-resolution ocean reanalysis data. On the shelf edge, the monthly mean OMLT is mainly determined by the monthly mean surface heat flux and the advection due to the monthly mean horizontal currents. The horizontal eddy and vertical shear terms are turned out to be minor. One shelf, the horizontal advection plays a secondary role. In addition to the surface heat flux, cooling effect that is probably due to entrainment across the base of the mixed layer becomes important during summer. (Abstract ID 10894)

HUMAN SENSOR NETWORKS FOR IMPROVED OIL SPILL PREDICTIONS

We describe the novel use of Human Sensor Networks (HSN) to augment the US response to extreme events. We capture Social Media (SM) data, and apply ensemble Kalman filter assimilation to incorporate the processed information into forecasting models. The system methodologies are applicable to the wider class of extreme events. A successful demonstration is shown for the Deepwater Horizon Oil Spill where HSN data are combined with satellite oil spill observations for assimilation in the general NOAA Operational Modeling Environment (GNOME). The GNOME model uses real-time surface winds, ocean currents, and satellite shape profiles of oil to forecast oil spill movement. Geolocated and timestamped Flickr images of beached oil were mined as boundary forcing conditions. We show that SM data can greatly supplement the current operational practice of sending out teams of humans to collect samples of tarballs reaching coastal locations. The combination of SM data and oil spill shape profiles generated by a Self Organizing Map algorithm can improve uncertain estimates of diffusive coefficients and rates of oil spill in the GNOME model parameterizations. INTEGRATING ANIMAL BORNE SENSORS WITH SMARTS CLIMATOLOGY MODEL IMPROVES FORECASTS OF HURRICANE INTENSITY AND FISHERY'S DYNAMICS

Hurricane intensity forecasting has been advanced by a new Systematically Merged Atlantic Regional Temperature and Salinity (SMARTS) Climatology model that blends temperature and salinity fields from the World Ocean Atlas 2001 and Generalized Digital Environmental Model at 1/4° resolution. The two-layer reduced gravity model framework facilitates robust daily estimates of isotherm depths from regional radar altimetry. In addition to tracking the depth of the 26oC isotherm for hurricane intensity forecasting, hundreds of Atlantic tarpon satellite-tagged with temperature-depth-salinity and GPS sensors have shown that tarpon closely followed this isotherm depth during their seasonal long-range migrations in the Gulf of Mexico and along the eastern seaboard. Tarpon sport-fishing is a $6 billion industry in the United States alone, but the resource is vulnerable to fishing and environmental changes. We explore how an enhanced network of animal-borne sensor deployments integrated within the SMARTS technology framework helps to improve understanding of the coupled dynamical behaviors of ocean-atmosphere and fish stock migrations that may portend a new era of forecasting hurricane intensity and novel ecosystem-based strategies for sustaining key ocean fisheries. QUANTIFYING SPATIAL RESOLUTION REQUIREMENTS FOR SATELLITE-BASED DETECTION OF BIOGEOCHEMICAL VARIABILITY IN RIVER PLUMES

Inter-pixel variability in satellite retrievals of biogeochemical properties at various spatial resolutions is used to investigate the optimal ground space distance (GSD) for the detection of total suspended material (TSM) river discharge during peak and minimum flow periods. Event driven, seasonal, and climatic fluctuations in river discharge and associated material fluxes have major implications for carbon budgets, fisheries and habitait, hyopxia, and pollution dispersal. Accurate detection of the extent and evolution of plumes will require adequate temporal, spectral, and spatial resolution in future ocean color missions such as Geostationary Coastal and Air Pollution Events (GEOCAPE). In this study, satellite data at the outflow of four major plume locations (Mississippi River, Susquehanna River, Chesapeake Bay, Amazon River, and Yangze River) were used to determine the resolution necessary to detect dispersion of TSM. Preliminary findings indicate that moderately high resolution retrievals (< 500 m) capture the majority of biogeochemical variability, while 1 km data misses significant variability. DECADAL TREND OF LONG-TERM CARBON SINK IN THE LABRADOR SEA

The Labrador Sea is one of two sites in the North Atlantic that produce intermediate and deep water by winter convection. Atmospheric CO2 that is taken up in the surface water is quickly transported to depths during deep convection and subsequently spreads to various regions of the North Atlantic. Some of this sequestered CO2 is incorporated into the meridional overturning circulation and stored in the deep ocean potentially for hundreds of years, thus, the Labrador Sea provides a conduit for long-term storage of atmospheric CO2. It is important to understand the size and variability of this CO2 sink in order to assess the role of the oceans in the global carbon cycle. We will present data showing the accumulation of atmospheric CO2 in the deep convection region along the Labrador Sea repeat section from 1996 to 2010. The inventory of DIC in the Labrador Sea was 106±14 PgC from the basin wide survey in 1997. The average inventory increase is 0.04 Pg C/year for the period from 1996 to 2010. The role of variable deep convection depths for uptake of atmospheric CO2 is discussed. (Abstract ID 9834)

COSEE-TEK TEACHER TECHNOLOGY EXPERIENCE: A CATALYST FOR LEARNING AND COMMUNICATING OCEAN SCIENCE AND TECHNOLOGY

The goal of COSEE-TEK is to improve ocean science education by highlighting the enabling role of technology and engineering in the ocean sciences and develop technology derived education and outreach resources to catalyze learning and communication of STEM topics for teachers, students, scientists, and the public. Educational resources illustrate the evolution of oceanographic technologies into complex integrated systems capable of addressing broader spatial and temporal scales. Three Teacher Technology Experiences (TTE) and a Teacher Ocean Technology Institute (TOTI) were held in 2011. The TTEs built teams of formal and informal educators working with scientists, graduate/undergraduate students and technicians from the University of Connecticut’s Department of Marine Sciences. The goals of the TTEs were to improve educators’ technology content knowledge, heighten scientists’ awareness of the challenges of science education and outreach and broaden the impacts of researchers science and technology by web-based educational resources. Evaluation results show a positive impact on both educators and scientist participants, including bringing scientific research into the classroom or informal venue, positive impacts on scientists’ view of education and ability to deliver quality broader impacts. SEDIMENT NITROGEN CYCLING FOLLOWING A SIMULATED DISCHARGE EVENT

A sediment / water mesocosm experimental design was used to investigate the response of nitrogen cycle processes to organic matter (OM) loading. The sequential changes in dissolved inorganic nitrogen (DIN) species in the overlying water after OM additions were followed in replicate tanks consisting of Chesapeake Bay sediments and overlying water. A Monte Carlo-based non-negative-least-squares model of stoichiometric finite difference equations was implemented to estimate the nitrogen transformation rates over the seven week experiment. Both the magnitude and timing of DIN fluxes differed between high and low OM treatments. However, the time required to remove the added nutrient load, and the proportions of net nitrogen loss via both denitrification pathways – anammox and denitrification – were the same, 71.9 ± 2.3% anammox, regardless of OM addition. This percentage of nitrogen lost via anammox was set by the nitrogen content of the organic matter amendment and the initial DIN concentrations. The in situ thermodynamic feasibility of all reactions was calculated, and the results suggested that thermodynamics, as well as carbon and nitrogen loading, control nitrogen processing in sediment ecosystems. INCLUDING HABITATS IN ESTIMATES OF UTILIZATION DISTRIBUTIONS FOR ACOUSTICALLY TAGGED REEF FISH

The estimation of generalized population parameters is a key aspect of population biology and, in both conservation and fisheries management of reef fish species, assessments of spatial usage are often an important part of the decision making process. Description of population-level movement parameters based on tracking data of acoustically tagged fish therefore presents a valuable tool for management. Here we present a novel approach to quantifying fish habitat utilization distributions using a combination of GLM and GAM based statistics which allows barriers to movement to be included and the role of habitat to be considered in the prediction of the utilization distribution. Using Spangled Emperor Lepturus nebulosus as a model species, the data reveal a range of habitat specializations within the population, as well as habitat-specific differences in the size of utilization distributions. These variations in behavior have important implications for management in the study area of Ningaloo Reef in Northwestern Australia, where marine park zoning currently under-represents several key habitat types. LIGHT-DRIVEN CARBON FLUXES IN THE ARCTIC OCEAN: SYNTHESIS OF THE RESULTS FROM THE MALINA PROJECT

In the Arctic, we are currently witnessing: 1) a decrease in summer ice cover that exposes sea surface to solar radiation and physical forcings, 2) permafrost thawing and increased river runoff, both of which lead to an augmentation of the export of organic carbon previously sequestered in the Tundra to the ocean, and 3) an increase in ultraviolet radiation. These three phenomena favour enhanced mineralization of organic carbon through photo-oxidation and bacterial activity, amplifying the increase in atmospheric CO2. At the same time, the exposure of a larger fraction of the ocean surface to sunlight, as well as the increase in nutrients brought by vertical mixing and river runoff, lead to heightened autotrophic production and sequestration of organic carbon. To predict the balance of these processes, we conducted an extensive study in the Mackenzie River / Beaufort Sea system in July, August and September 2009 aboard the Canadian research icebreaker CCGS Amundsen. The spatial distribution of organic carbon stocks (living and detrital) in the water column and sediments was assessed on the shelf and beyond. The magnitude and variability of organic carbon mineralization through photo-oxidation and bacterial activity, in addition to that produced through photooxidation were determined. A detailed study of microbial biodiversity was also conducted. A synthesis of the project’s results will be presented. (Abstract ID 10960)

CONTRIBUTIONS OF PICOPHYTOPLANKTON TO PRIMARY PRODUCTIVITY AND BIOMASS IN MESOSCALE EDDIES IN THE SARGASSO SEA

On two 14-day cruises in the Sargasso Sea we measured size-fractionated primary productivity and phytoplankton biomass (as chlorophyll a) at the center, edge, and outside a warm-core eddy (Feb–Mar 2011) and a cold-core eddy (July–Aug 2011). Total euphotic zone integrated primary productivity was highest in the winter at the edge of the warm core eddy (188 mgC m−2 d−1) and outside the eddy at the BATS station (160 mgC m−2 d−1). Lowest rates were observed outside the cold core eddy (also at BATS) in summer (60 mgC m−2 d−1). Picophytoplankton contributed 56 to 93% of the total primary productivity. At three stations, the relative contributions of the picophytoplankton to productivity were directly proportional to their contributions to biomass. At four stations, picophytoplankton contributed disproportionately to productivity (66 to 93% of the total) as compared to their contributions to biomass (41 to 76%). These data will be incorporated into plankton size-specific models of trophic dynamics and carbon cycling in the Sargasso Sea. (Abstract ID 9956)

A MESOSCALE EDDY PARAMETERIZATION CHALLENGE SUITE: EADY-LIKE MODEL RESULTS

An “eddy parameterization challenge suite” is being developed, consisting of a set of high-resolution tracer experiments designed to assist in parameterizing subgrid-scale processes in ocean models. In each experiment, multiple tracers are initialized in a frontal standdown simulation which is designed to mimic the stirring effect of mesoscale eddies. The tracer data are used to infer the strength of advective and diffusive effects induced by the eddies. Several hundred such experiments varying in Rossby number, Richardson number, and other parameters, can therefore tell us how mesoscale eddies redistribute tracers in many different flow settings, and can help inform a skillful parameterization of these effects. Results are presented from a set of Eady-like simulations, including scaling laws and vertical structures of the stirring and diffusion. (Abstract ID 10664)

THE ARCTIC OCEAN IN SUMMER: A NEAR-SYNTHETIC INVERSE MODEL OF BOUNDARY FLUXES OF HEAT, FRESHWATER AND NUTRIENTS

The near-synthetic estimates of Arctic Ocean and sea ice net fluxes of heat, freshwater and nutrients are calculated using an inverse model. Hydrographic measurements from four gateways (Bering, Davis and Fram Straits, and the Barents Sea Opening) completely enclose the ocean, and were made in the same 32-day period in Summer 2006. The inverse model is based on density layers from temperature and salinity profiles, and includes representations of Fram Strait sea ice export and of interior Arctic Ocean vertical fluxes. The inverse model is initialised with velocity profiles measured by ship-mounted and moored instruments. Volume and salinity transport constraints are applied. In summer 2005 the transport-weighted mean properties are, for water entering the Arctic: potential temperature 3.29°C, salinity 34.62 and potential density (sigma0) 27.56 kg/m3 for water leaving the Arctic, including sea ice: 0.72°C, 34.20 and 27.42 kg/m3, respectively. The Arctic in summer freshens and cools the inflows by 0.42 in salinity and 2.56 °C, and decreases density by 0.13 kg/m3. The volume transport into the Arctic of waters above ~1000 m depth is 8.3 Sv (1 Sv = 106 m3/s) for water entering the Arctic: potential temperature 3.29°C, salinity 34.62 and potential density (sigma0) 27.56 kg/m3; for water leaving the Arctic, including sea ice: 0.72°C, 34.20 and 27.42 kg/m3, respectively. The Arctic in summer freshens and cools the inflows by 0.42 in salinity and 2.56 °C, and decreases density by 0.13 kg/m3. The volume transport into the Arctic of waters above ~1000 m depth is 8.3 Sv (1 Sv = 106 m3/s), the export (similarly) is 8.3 Sv; the net surface freshwater input is 180±6 m6. Non-stationary components of the freshwater budget are estimated separately. The net heat flux (including sea ice) is 182±26 TW. Net nutrient exports are 0.2 (nitrate), 0.09 (phosphate) and 1.49 (silicate) kmol/m3. (Abstract ID 11060)

NITROGEN UPTAKE DYNAMICS IN ARCTIC LANDFAST ICE

We quantified nitrogen transformations by natural sea-ice communities using stable isotope techniques. In the Spring of 2011, ice cores were taken off the coast of Barrow, Alaska in conjunction with a study on water column nutrient dynamics. The cores were divided into three 10 cm sections centered on 5, 20 and 35 cm above the ice-water interface. After melting, subsamples from each depth were incubated with either N-15 labeled ammonium, nitrate, or urea. Absolute uptake of ammonium and nitrate were significantly higher in the 5 cm section, while the other depths were comparable to water column rates. Bacterial productions (using C14-leucine incorporation) showed a similar pattern, with significantly higher rates in the 5 cm fraction and rates comparable to the water column in the higher sections of ice. Unlike the community present in the water column, heterotrophic bacteria were well represented in the ice. This novel approach to sea-ice biogeochemistry suggests that substantial nitrogen transformations occur during the spring thaw. (Abstract ID 10435)

MODELLING CIRCULATION AND THERMAL STRUCTURE IN THE GREAT LAKES WITH FVCOM

An unstructured Finite Volume Coastal Ocean Model (FVCOM) was applied to all the five Great Lakes to simultaneously simulate circulation and thermal structure over a seasonal cycle. Lakes Michigan, Huron, St. Clair and Erie were connected, while Lakes Superior and Ontario were kept disconnected with others due to the nature of human management. 3 hourly winds, air temperature, specific humidity and cloudiness from the North American Land Data Assimilation System (NLDAS) were used to force the model. The model results were compared to available water temperature observations (Satellite Obs, moorings and buoys). Seasonal evolution of general circulation and thermal structure, and response of each lake to atmospheric forcing were investigated. (Abstract ID 9477)

COMMUNICATING SCIENCE TO DECISION MAKERS: PERSPECTIVES FROM A RECOVERING MANAGER OF OCEAN AND COASTAL POLICY

Ocean and coastal science should be the foundation of sound public policy, but often it is not. Ongoing challenges such as climate change, habitat disruption, declines in marine resources, water quality degradation, and the erosion of our coastlines continue to plague governments at the international, national, regional, state, and local levels. Decision makers need to understand these issues and to develop effective, efficient, and feasible ways to address them. However, bringing science to management is not always easy or straightforward. Can researchers provide science in a manner that can be understood by decision makers? Do decision makers pose clear questions to the science community? Is there sufficient time and money to address the science? Can scientists remain objective while advocating for a certain point of view? This presentation will provide case studies of efforts from multiple levels of government to communicate science that is intended to be applied to ocean and coastal decision making. It will highlight the emergence of “boundary” organizations intended to bridge the gap between the science community and decision makers. (Abstract ID 10018)

COMPONENT-SPECIFIC ANALYSES OF CORAL AMINO ACIDS SHED LIGHT ON A THREATENED SYMBIOSIS

While some cridarians are able to synthesize most essential and non-essential amino acids, studies have shown that zooxanthellae are the primary source of these building blocks in symbiotic species. Our carbon isotope data of zooxanthellae-derived amino acids confirms this with the exception of serine, which is enriched in the symbiont. “Coral bleaching”, the breakdown of the coral-algal symbiosis due to temperature and light stress, results in the expulsion of zooxanthellae, leading to starvation and death of the coral host and is increasing globally as sea surface temperatures rise. Here, we present data comparing two symbiont types (thermally sensitive and thermally tolerant) within the same coral host, Acropora tenuis from the Great Barrier Reef, Australia. When exposed to sub-bleaching temperatures in the presence of HCO3−, thermally sensitive clades suffer a 16 % drop in carbon fixation, while tolerant types are unchanged. Amino acid data illustrate a decoupling of amino acid transfer from symbiont to host. While hosts of either symbiont were indistinguishable in their enrichment profile, symbionts were dissimilar, illustrating that amino acid synthesis is impaired in sensitive types. OBSERVATION AND SIMULATION OF TURBULENCE IN THE OCEAN SURFACE BOUNDARY LAYER

Upper ocean variability in response to surface wave forcing is studied using field observations and numerical model simulations. Observations include data reported in previous studies as well as new measurements obtained from an experiment during 8-13 April 2011 in the Vestfjorden, Norway. Near surface turbulence observations were made at about 11 m below the surface using instruments fitted in a low-drag buoy at the top of a bottom-anchored mooring line. This instrument buoy measures small scale shear, temperature fluctuations, platform body vibrations, pitch, roll, and heading as well as 3D velocity fluctuations. The mooring line includes two temperature-conductivity loggers and an uploading 3000 kHz acoustic Doppler current profiler for background current measurements. Bearing record of the buoy shows that the instrument satisfactorily aligns with the mean current. For numerical modelling, a one-dimensional ocean model is modified to include surface wave stress, wind energy input, wave dissipation and Stokes drift to study the effects of wave forcing and breaking. The skull of the model in simulating the near surface wave enhanced layer and the turbulent kinetic energy budget will be discussed. (Abstract ID 11015)

DEVELOPMENT OF SMOS LEVELS 3 AND 4 SEA SURFACE SALINITY MAPS

Sea surface salinity (SSS) maps are generated at the Spanish SMOS Level 3 and 4 Data Processing Centre (CP34) by using objective analysis interpolation (Level 3) and data fusion techniques which combine the SMOS data with other satellite observation types (e.g., AMSR-E sea surface temperature data or Aquarius SSS data). Present efforts on L3 at CP34 are focused on the application of Objective Analysis on L2 data to produce L3 maps. The correlation matrices required by Objective Analysis have been generated using different model outputs. Ongoing work on L4 production aims to data fusion techniques based on the use of singularity analysis to exploit data synergy. Singularity analysis gives a numerical estimate of the local regularity (singularity exponents) of an ocean variable at all the points, as singularity exponents are a characteristic of the flow, not specific to the variable. The information provided by singularity exponents is then used to reconstruct SSS fields satisfying the multi-scale characteristics of geophysical flows. Data fusion of SMOS with microwave SST, surface chlorophyll concentration, and Aquarius data are calculated. L3 and L4 maps are validated with near-surface measurements provided by Argo profilers. We have found that the implementation of these techniques significantly improve data accuracy with respect to L2 maps. (Abstract ID 11035)
where euphausiids contribute little to vertebrate production. All regions showed large potential in microzooplankton had greatest effect on GB vertebrate predators. Reduced euphausiid μm) vs large (>20 μm) phytoplankton production; increased microzooplankton production at functional groups in response to climate change. Simulations include: increased small (< 20 μm) vs large (>20 μm) phytoplankton production; increased microzooplankton production at competitive expense to other zooplankton grazers; and reduced euphausiid production with surplus phytoplankton production benefitting copepods and gelatinous zooplankton. Changes in phytoplankton groups had greatest impact on SO top predator production while changes in microzooplankton had greatest effect on GB vertebrate predators. Reduced euphausiid production affected upper trophic level production in SO, NCC and CGoA but not in GB where euphausiids contribute little to vertebrate production. All regions showed large potential impacts from changes in the plankton assemblage size composition. (Abstract ID 12166)
Nighttime and Daytime-Only Optimally Interpolated SST Analyses

A Climate Data Record (CDR) time series must be "of sufficient length, consistency, and continuity to determine climate variability and change." To meet these requirements, a nighttime-only optimum interpolation (OI) sea surface temperature (SST) analysis product is being developed at NCDC, using the new Pathfinder AVHRR SST v5.2 release. The Pathfinder dataset uses afternoon satellites (NOAA 7, 9, 11, 14, 16, and 18) for the entire period (1981–2010), except in 2002–2005 when only the morning satellite NOAA 17 was functioning properly. Prior to analysis, the satellite data is adjusted to in situ data to minimize biases. The methodology is similar to that of the current operational NOAA daily’s deg OISST except that day- and nighttime data are analyzed separately. The minimal impact of diurnal variability on the nighttime-only product makes it a good CDR candidate. The separate day/night OISST analyses also offer better reference fields for evaluating satellite SST algorithms. Particular challenges occur at high latitudes where seasonal daylength fluctuations affect the amount of nighttime and daytime in situ data. Possible algorithm adjustments are examined. (Abstract ID 10573)

Adaptive Sampling Strategies to Characterize MicrObial Communities in a Dynamic Estuary

The Center for Coastal Margin Observation & Prediction studies the response of coastal margins to changing climate and ocean and river conditions, using the Columbia River as a testbed. In order to understand the estuary’s potential role as a ‘bioreactor’ that modulates river-to-ocean exchanges, we focus on characterizing biological hotspots. To investigate how microbial communities influence these hotspots, we will deploy an Environmental Sample Testbed. VENTILATION CHARACTERISTICS OF THE CESM OCEAN COMPONENT

The ventilation properties of the ocean component of the Community Earth System Model (CESM) are analyzed using simulations of radiocarbon, CFC-11, CFC-12, ideal age, and water mass fraction tracers. The tracer simulations are computed efficiently using an offline tracer-transport model formulated in terms of a sparse matrix tracer transport operator. Steady-state tracer fields are obtained by directly inverting the transport operator while transient tracers are simulated using a fully implicit time-stepping scheme that allows us to take large time-steps. The simulated tracers are compared to GLODAP observations and to the data-assimilated circulation model of DeVries and Primeau (2011). (Abstract ID 11769)

ROTATING HORIZONTAL CONVECTION

“Horizontal Convection” (HC) is the generic name for the flow resulting from a buoyancy variation imposed along a horizontal boundary of a fluid. We study numerically the effects of rotation on HC, concentrating on changes to boundary layer scalings, deep stratification and overall energetics of the flow. With the Meridional Overturning Circulation in mind, we consider a rectangular box with insulating conditions on the meridional sides and bottom, periodic conditions on the zonal sides and a fixed buoyancy flux on the top. The rotation rate varies smoothly over the meridional extent of the domain. We follow the classification of Hignett et al. (1981) based on a parameter Q relating thermal to Ekman scales and examine the “medium” regime with Q – 1, as well as the modifications for Q – 1, i.e., when the thermal scale is larger than the Ekman scale. The effects of baroclinic instability are analyzed using the spatial distribution of Available Potential Energy and Kinetic Energy densities. (Abstract ID 10495)

AQUATIC LASER FLUORESCENCE ANALYZER (ALFA): A NEW INSTRUMENT FOR CHARACTERIZATION OF NATURAL AQUATIC ENVIRONMENTS

The Advanced Laser Fluorometry (ALF) is a new technique to quantify and characterize key aquatic constituents, including chlorophyll, phycoerythrin and variable fluorescence of phytoplankton, as well as colored dissolved organic matter. It provides real-time in vivo fluorescence assessments of phytoplankton biomass, photophysiology and composition to assess the quality and health of aquatic ecosystems. Development of the commercial ALFA and ALF In Situ (ALFIS) instruments has been recently sponsored by NOPP to operationally implement the ALF technique and provide new means for aquatic research and environmental monitoring. Several ALFA prototypes have been developed in collaboration between LDEO, WET Labs and SIO. The light-weight, compact, portable flow-through ALFA instrument provides high-resolution shipboard underway measurements for characterization of meso- and synoptic-scale horizontal distributions, as well as analysis of discrete water samples. Improvements have been made to simplify the system design, maintain optical alignment, and improve serviceability. The ALFA instrument can be customized for single or multiwavelength fluorescence excitation, as well as spectrally and/or temporally resolved measurements. ALFA fluorescence excitation, as well as spectrally and/or temporally resolved measurements. ALFA improves serviceability. Development of the commercial ALFA and ALF In Situ (ALFIS) instruments has been recently sponsored by NOPP to operationally implement the ALF technique and provide new means for aquatic research and environmental monitoring. Several ALFA prototypes have been developed in collaboration between LDEO, WET Labs and SIO. The light-weight, compact, portable flow-through ALFA instrument provides high-resolution shipboard underway measurements for characterization of meso- and synoptic-scale horizontal distributions, as well as analysis of discrete water samples. Improvements have been made to simplify the system design, maintain optical alignment, and improve serviceability. The ALFA instrument can be customized for single or multiwavelength fluorescence excitation, as well as spectrally and/or temporally resolved measurements. ALFA field tests in the Pacific Ocean and coastal zone of California are analyzed. (Abstract ID 11217)

ESTOC SITE: IMPROVING ITS PERMANENT TIME-SERIES OCEAN OBSERVING PROGRAM WITH UNDERWATER GLIDERS

In-situ ocean observations have been traditionally carried out through oceanographic ships, VOS, moorings, drifters and floats mainly. All of them are able to sample water column biogeochemical parameters (coastal and off-shore areas) but not always within the right spatial-temporal resolution, operational and cost-effective required ratio. Nowadays, cutting-edge technology tools allow to have autonomous and permanent ocean sites furnished with multidisciplinary observing platforms and sensors, sampling and providing product-information to the end-users in real-time mode. The European Station for Time-series in the Ocean–ESTOC-, as OCEANsite's network member and consolidate ocean site reference in the Eastern Central Atlantic for more than fifteen years of multidisciplinary time-series background, has recently improved its biogeochemical sampling program with the main three underwater gliders technology available. This new approach is the result of a collaborative effort between the Oceanic Platform of the Canary Islands–PLOCAN- and the Marine Sciences Institute of Canary Islands (ICCM) where PLOCAN is in charge to provide all the technical and operational logistics required by the end users for their scientific aims, managed by ICCM through its Oceanography's Department. OPERATIONAL NAVY OCEAN FORECASTING USING ISOP PROJECTION OF SATELLITE ALTIMETRY AND SURFACE TEMPERATURE

Operational ocean forecasting over global and regional domains requires satellite data to ensure sufficient prediction accuracy. The daily spatial sampling of in situ profiles is about 4 orders of magnitude less than the coverage of satellite altimeter and surface temperature. Under the Improved Synthetic Ocean Profiles (ISOP) effort, we leverage extensive climatological records of in situ observations to develop variational models relating satellite observations to subsurface predictions. These vertical projections are incorporated into the Navy Coupled Ocean Data Assimilation System (NCODA) for use in global and regional Hybrid Coordinate Ocean and Navy Coastal Ocean models (HYCOM and NCOM). Validation studies using independent profile observations compare model analyses and forecasts based on ISOP with forecasts using prior operational capabilities. These results indicate that ISOP-based assimilation of satellite altimeter and surface temperature reduces forecast errors in the temperature, salinity, and acoustic forecasts supporting Navy operational applications. EFFECTS OF OXYGEN AND pH ON THE PERFORMANCE OF THE URCHIN STRONGYLOCENTROTUS FRAGILIS ACROSS A DEPTH GRADIENT SPANNING THE OXYGEN MINIMUM ZONE

Along the N.E. Pacific coast, the fragile urchin, Strongylocentrotus fragilis has a bathymetric range (200-1200 m) that straddles the oxygen minimum zone (OMZ), and thus, tolerates a broad range of oxygen and carbonate chemistry. S. fragilis attains a larger size at the shallow end of its range, suggesting that the population grows and survives better in this zone, which differs in oxygen and pH, but also several other factors (e.g., temperature, food) from deeper waters. We examined the effects of oxygen and pH on metabolic performance and behavior using in situ manipulative experiments and laboratory studies. Changes in oxygen levels had the largest effect on urchin metabolism, particularly near severe hypoxia (=10 umol O2 kg-1 SW). Acidification had significant, but milder effects on metabolism, but also inhibited feeding below pH – 7.2. These results suggest that oxygen is limiting within the core of the OMZ, and that decreasing pH may also affect S. fragilis as ocean acidification intensifies in the future. Ongoing long-term studies indicate that S. fragilis may have significant capacity for acclimation to acidification over several months. (Abstract ID 12279)

THE EFFECTS OF OCEAN ACIDIFICATION ON MARINE BENTHIC ORGANISMS AND PROCESSES

Ocean acidification can affect a variety of biological and biogeochemical processes which, in turn, may have important consequences for the structure and function of marine benthic ecosystems and related benthic processes. This talk provides an overview of biological effects of ocean acidification on benthic organisms and processes, and examines potential consequences of future increases in acidification and related environmental changes. Ocean acidification can cause physiological stress for marine benthos, such as impaired calcification, disruption of
acid-base balance, and respiratory stress, with potential consequences for growth, survival, and reproduction. Vulnerability of key groups such as habitat forming species (e.g. corals) or dominant bioturbating taxa in marine sedimentary habitats, may lead to significant changes in ecosystem structure as well as biochemical exchanges. What benthic systems or processes are most likely to be altered as pH and carbonate saturation decline through this century? Are coastal systems more vulnerable than deep-sea benthos? Will changes in carbonate saturation or potential shifts in benthic infaunal assemblages carbon burial in marine sediments? (Abstract ID 12200)

HYPOXIA OVER THE CONTINENTAL SHELF IN THE NORTHEAST PACIFIC OCEAN

Over the last decade, severe hypoxia (dissolved oxygen less than 0.5 ml/l) and even anoxia have been observed during the late summer upwelling season in near-bottom waters off the central Oregon coast. We use historical data and recent underwater glider and ship surveys to describe the temporal and spatial variability of hypoxia in Oregon coastal waters. Waters with the lowest oxygen values are found over the mid shelf (~80-100 m) as a result of upwelling of low-oxygen water onto the shelf, followed by decay of organic matter raining down from surface phytoplankton blooms. Dissolved oxygen measurements from 6 years of underwater glider transects are used to explore year-to-year variations in the extent of near-bottom hypoxia. Both the dissolved oxygen concentrations of the upwelled source waters and local winds explain variability in near-bottom shelf hypoxia. Oxygen in the upwell source waters (26.5 kg/m^3) has declined by 0.6 ml/l over the last 50 years. Recent near-bottom data collected by a variety of platforms reveals a ribbon of hypoxic near-bottom water at mid shelf all along the Pacific Northwest. (Abstract ID 10712)

VENUS: LIVE DATA FROM A COASTAL OBSERVATORY

Ocean observatories have been designed with continuous real-time data transmission as a key feature. Collecting, storing, archiving, and then re-distributing the data over the Internet in near real-time represents its own set of challenges. VENUS has developed a suite of solutions for representing the data in various native and standard formats, including numerical values, automated data plots, and even streaming audio and video presentations. The interactive displays will highlight various live data streams from multiple sites and instruments across the network. Demonstrations of the data retrieval tools for exploring the archive and extracting data products, including metadata, will also be presented. (Abstract ID 10057)

REGIONAL VARIATIONS IN THE SEASONAL SUCCESSION OF DIATOMS AND DINOFLAGELLATES IN THE NORTH ATLANTIC

We present a trait-based analysis of regional variations in seasonal patterns of abundance for diatom and dinoflagellate taxa observed by the Continuous Plankton Recorder survey of the North Atlantic, whose cell size and trophic strategy are the traits of interest. The spring peak in diatom abundance precedes a summer dinoflagellate peak throughout the survey area, and peaks of abundance for both taxonomic groups are later and stronger at higher latitudes. Smaller diatoms are relatively more abundant in summer and larger diatoms are relatively more abundant in winter. This pattern occurs over a range of latitudes and we hypothesize that the relatively high nutrient affinity of smaller diatoms leads to their dominance during nutrient-deplete conditions. When the dinoflagellate taxa are differentiated by trophic strategy we find that mixotrophs lead heterotrophs in ecological succession in oligotrophic seas by up to two months, whereas there appears to be no such differentiation at higher latitudes. We hypothesize that the ecological niche for mixotrophs is evident in oligotrophic seas because mixotrophs can successfully compete in resource-scarce conditions by acquiring both inorganic and organic nutrients. CANARY CURRENT UPEWELLING: MORE OR LESS?

It has been hypothesized that coastal upwelling is increasing globally as a consequence of warming climate. Recent research has suggested a significant increase of upwelling intensity off Northwest Africa on the basis of proxy sea surface temperatures from alkenone unsaturation index (UK37) analysis of sediment cores off Cape Ghir, Morocco. An accelerating decrease in excess of 1°C over the last century was concluded for surface temperature near the Cape. Support was found in an increase in Bakuri’s upwelling index for the latitude of the Cape. We examine evidence for a general intensification of upwelling within the whole Canary current upwelling system. Using available estimates of wind from PFL, NCAR/NCEP ECMWF, ICOADS and WASWind plus meteorological stations, we find no evidence of a coherent wind intensification at the regional scale off Northwest Africa. Moreover, ICOADS surface temperature records since 1967 and Pathfinder AJHRR data from 1986 show a significant and correlated warming in all the region. We conclude there is no evidence for a general increase in upwelling intensity off Northwest Africa or Iberia. Reasons for the difference between the proxy temperature indicated by the alkenone unsaturation index and the observed sea surface temperature off Cape Ghir are explored. (Abstract ID 11730)

HIGH-RESOLUTION IN SITU AND AERIAL MEASUREMENTS OF SUBMESOSCALE EDDIES, FRONTS, AND FILAMENTS

In order to truly resolve the small scales of submesoscale eddies and fronts, we have collected high-resolution (1-15m) in situ and aerial data during the submesoscale experiment SubExI off Catalina Island, CA, in April 2011. Repeat measurements every 15-30min enabled us to observe significant changes over very short time scales and to investigate the temporal evolution of these features. Measurements were taken in a collaborative effort with aerial IR, hyperspectral, and SAR imagery from 3 planes, as well as in situ measurements with a Towed Instrument Array (TIA), drifters, currents, surfactants, and optical measurements. The temperature and salinity data collected with the TIA have a vertical and horizontal resolution of 1-5m covering the upper 35m of the water column at a tow speed of 4-5m/s demonstrating that the observed submesoscale features mostly occur within a shallow, 5-15m deep thermocline. Fronts are very sharp with temperature and density gradients of 1°C and 0.2kg/m^3 over 5m. The observed features evolve over the course of a few hours. Rotational and advective velocities are 0.2-0.4 m/s resulting in a large Rossby number flow. (Abstract ID 12061)

PARTICLE TRANSPORT MODELING OF SMALL RIVER PLUMES OFF CALIFORNIA APPLIED TO MARINE PATHOGEN FATE

The focus of our work is on transport and dispersion of Toxoplasma gondii oocysts delivered to coastal waters via small river plumes. T. gondii is a zoonotic pathogen that has a very high incidence of disease in California sea otters along the Central California Coast. Previous work found that oocysts were effective at trapping T. gondii oocysts. In this study we explore how particle fate differs when these organisms are delivered directly to the ocean via small coastal streams. Preliminary model results are presented from an implementation of the Regional Ocean Modeling System (ROMS), a three-dimensional, free-surface, terrain-following numerical model that includes a particle tracking using Larval Transport Lagrangian model (LITRAN). In these preliminary results we explore the distribution of oocysts based on the assumption that they are passive neutrally buoyant particles. Transport dynamics of this pathogen are analyzed under varying flow conditions and variable coastal circulation. (Abstract ID 12161)

TOS/AGU/ASLO Abstract Book
In the second experiment, larvae were placed in arenas containing either fine sand (0.2 mm) or gravel (3 mm) to examine whether different grain sizes delayed settlement. In the first experiment, larvae demonstrated a statistically significant preference for finer substrates. Larvae in the second experiment delayed settlement significantly when exposed to coarse substrate. Collectively, these data suggest behavior is an important component of the settlement dynamics in Northern rock sole. This insight allows for future analysis of the other components that may affect this critical, largely understudied process. (Abstract ID 12512)

THE EFFECTS OF DEEPWATER HORIZON CONTAMINATION ON MICROBIAL COMMUNITY STRUCTURE AND BIOGEOCHEMICAL CYCLING IN OIL IMPACTED GULF OF MEXICO

Bacterial-phytoplankton interactions are governed by tightly coupled processes that drive the microbial food web. Oil may provide an additional carbon substrate to support bacterioplankton production. Oil could, however, inhibit phytoplankton production resulting in a decoupling of bacterial-phytoplankton processes. Both the addition of oil and the decoupling could result in a shift in the microbial community structure and alter other biogeochemical cycles. To evaluate how microbial processes are impacted by hydrocarbon inputs, we conducted time series investigations on bacterial microcosms responsive to oil dispersant versus whole water sample collected across a coastal oil contamination gradient (i.e. heavily-contaminated to pristine). For the pristine site, initial increases in bacterial abundances were observed within the first day in samples amended with dispersant only, after which they decreased. Automated Ribosomal Intergenic Spacer Analysis (ARISA) reveals fairly tight clustering for microbial groups in all amendments in both the heavey and moderately impacted sites when compared to the pristine site suggesting prior adaptation to oil exposure at the contaminated sites. (Abstract ID 12421)

ROLE OF ADVECTION IN DEVELOPMENT OF CIRCULATIONS CAUSED BY INTERACTION OF SURFACE WAVES AND INHOMOGENEOUS CURRENTS

The effect of advection on paired circulations, generated by the interaction of long surface waves with non-uniform currents, is considered. The circulations are caused by a vortex force imposed by the surface waves on an inhomogeneous current, and are similar in nature to Langmuir circulations. The circulations are convergent when the direction of propagation of the waves coincides with the current direction and divergent when the directions of waves and current are opposed. At the initial stage of development, the converging and diverging circulations have same structure. Once advection affects the initial current, converging circulations become more narrow and the diverging circulations become wider. This effect is illustrated for a near-surface current such as the model of a ship wake and for a deeper underlying jet such as a river or sewer outflow. Similar circulations can be generated for many types of currents: therefore the effect of the vortex force on a non-uniform current should be taken into account when the current is within the influence of strong ambient surface waves. (Abstract ID 12207)

Bas, P., Gulf of Mexico Alliance, Biloxi, USA, phil.bas@gomox.org

GULF OF MEXICO ALLIANCE

The Gulf of Mexico Alliance (GOMA), founded in 2004, is a partnership between the five Gulf states (Alabama, Florida, Louisiana, Mississippi, and Texas), key federal agencies, academia and non-governmental organizations with the goal of increasing regional collaboration to enhance the ecological and economic health of the Gulf of Mexico. The Alliance focuses on six priority issues that can be addressed through greater coordination at the local, state and federal levels. With the support of federal and non-governmental partners, the Alliance has developed a true regional approach in undertaking actions to improve the health of coastal ecosystems and economies of the Gulf. In 2009, the Governor’s Action Plan II (APII) was developed, building on the successes of the first Action Plan. API II is a further-reaching, five-year regional plan that looks to expand strategies and partnerships. The core goals of the first Action Plan were to build a foundation for a regional approach. The API II sets a course for specific actions designed to improve the health and coastal ecosystems of the Gulf in ways that a single entity could not. (Abstract ID 12894)

AMBIENT NOISE FROM GRAVEL AND COBBLES SHIFTING UNDER FAST CURRENTS

Measurements of near-bed currents and ambient noise from Admiralty Inlet, WA (USA) are presented. Tidally driven currents at the site, approximately 60 meters deep, exceed 3.5 m/s. The seabed is primarily composed of gravel and small cobbles (diameter < 10 cm). Strong currents are correlated with increased sound levels at frequencies (2-25 kHz) consistent with coarse-grain bedload transport. Flow noise, or pseudosound, is significant in the recordings, but only at lower frequencies (< 1 kHz). Seabed video from the site confirms mobilization of coarse sediments. The critical shear stress for bed mobilization is estimated to be on the order of 6 Pa. When near bed (z = 1.5 m) currents exceed 1 m/s, the minimum recorded sound pressure level in the 2-25 kHz band begins to increase. At peak currents, sound pressure levels in this band are more than 20 dB higher than typical slack tide conditions and significantly higher than levels attributed to anthropogenic noise sources in the area. We investigate critical shear stresses and the empirical relationship between bed stress and noise generated by the moving cobbles. (Abstract ID 10609)

BUILDING A GLOBAL NETWORK FOR SUSTAINABILITY-SCIENCE IN LARGE MARINE ECOSYSTEMS (LMES)

NOAA's global network of 64 LMEs provides a framework for sustainable ecosystem-based management in ecologically bounded transnational areas. LMEs produce 95% of the world’s annual marine fishery biomass yields. The US National Ocean Policy designates nine LMEs as the regional governance venues for CMS and EBM to support protection, maintenance, and restoration of the health and biological diversity of the ocean, improved resilience, and increased conservation and sustainability. Understanding and sustainably managing the interactions between humans and marine ecosystems face fundamental difficulties. A major impediment to the more sustained use and conservation of LMEs is the disconnect between practitioners of human and natural science, and resource managers and policy makers. An innovative network using modern semantics and informatics coupled to a social-ecological systems approach that engages those with expertise on marine systems, governance, and sustainability science as well as members with the policy and intergovernmental community is key to building the trust and understanding needed among practitioners, scientists, and stakeholders. Sustained end-to-end engagement of diverse practitioners will ensure that best available science is effectively used in management and policy-making. (Abstract ID 12158)

TWO-PHASE EULER-LAGRANGE SIMULATIONS FOR SHEET FLOW TRANSPORT OF MIXED-SIZE SEDIMENTS

Intense collision-dominated bedload transport under sheet flow conditions is thought to be the primary agent of nearshore bathymetric evolution. We model sheet flow transport with two-phase flow simulations using a Reynolds-Averaged Navier Stokes (RANS) fluid solver for turbulent flow coupled to a Discrete Element Method (DEM) for modeling the motions of individual sediment grains. The RANS fluid solver uses a k-ε turbulence closure and solves a one-dimensional in the vertical (1DV) profile. The coupled RANS-DEM simulations include viscously damped collisions at low Stokes numbers and turbulent suspension implemented through an eddy-particle interaction model based on a random walk. Simulations of sheet flow transport were performed under oscillatory forcing conditions with a variety of grain size distributions, including mixtures of coarse (D50 = 0.51 mm), medium (D50 = 0.28 mm), and fine (D50 = 0.13 mm) sediment. Model results are generally in good agreement with laboratory measurements for bulk transport rates and time-dependent concentration and velocity profiles within the sheet flow layer. Discussion will focus on utilizing simulation results to estimate the time-averaged near-bed sediment concentration commonly used in pickup functions. (Abstract ID 11584)

USING AN EMBEDDED LAGRANGIAN MODEL TO REPRESENT DOWNSLOPE FLOWS IN LEVEL COORDINATE OCEAN CLIMATE MODELS

Hydrostatic ocean models are known for their relatively poor representation of some climatically important processes. For example, downslope flows play a key role in the
sinking branches of the meridional overturning circulation, yet the present generation of ocean climate models poorly resolve the associated physics. In particular there is a spurious dilution of overflows and gravity driven currents are generally broad and sluggish, often failing to penetrate to realistic depth. In this study an embedded Lagrangian model to represent downwelling flows has been developed and implemented in the GFDL Modular Ocean Model. The Lagrangian model has been tested in several idealized configurations, showing significant differences with traditional parameterizations. In the DOME configuration, which is a gravity driven plume on a uniform slope, use of the embedded Lagrangian model increases the downwelled component of the plume’s transport while, under the influence of rotation, also increasing the along slope speed of the plume. These changes improve some of the shortcomings of coarse resolution level models for representing downwelling flows. (Abstract ID 10511)

REDUCED EARLY LIFE GROWTH AND SURVIVAL IN A FISH IN RESPONSE TO ELEVATED CO₂ LEVELS

A growing body of empirical evidence suggests that ocean acidification will challenge a suite of marine organisms in complex ways. While research is already well advanced for organisms that synthesize calcareous exoskeletons or shells, it is still insufficiently understood, how fish might be affected by ocean acidification. Although juvenile and adult fish tolerate short-term exposures to CO₂ levels that exceed those predicted for the next 300 years, recent studies on fish early life stages have found detrimental behavioral responses or abnormal otolith growth under exposure to elevated CO₂ concentrations. The current laboratory study is, to our knowledge, the first to demonstrate direct adverse growth and survival effects in the early life stages of a common estuarine fish (Menticirrhus beryllina) resulting from exposure to CO₂ concentrations expected in the world’s oceans later this century. Compared to present day CO₂ levels (~400 ppm), exposure of M. beryllina embryos to ~1,000 ppm until one week post hatch reduced average survival and length by 74% and 18%, respectively. The egg stage was significantly more vulnerable to high CO₂-induced mortality than the post-hatch larval stage. These findings challenge the belief that ocean acidification will not directly affect fish populations, because even small changes in early life survival can generate large fluctuations in adult fish abundance. (Abstract ID 10804)

SEASONAL PARTICLE RETENTION ON THE EASTERN BERING SEA SHELF EVALUATED USING TH-224

Water column and sediment ²³⁴Th distributions were measured at approximately 60 stations over the shelf and slope regions of the eastern Bering Sea during spring and summer in 2009 and 2010. Using the ²³⁴Th focusing factor (²³⁴Th-FF), inference are made with regard to seasonal retention of particulate ²³⁴Th over the shelf and boundary scavenging at the ocean margin. An average ²³⁴Th-FF of 1.1 ± 0.7 over the eastern Bering Sea shelf indicates that, over seasonal time-scales, particulate ²³⁴Th is retained in shelf sediments and not exported to slope/basin sediments. In contrast, ²³⁴Th-FFs of up to 8 were determined for the slope region, which are attributed to boundary scavenging of ²³⁴Th transported from the interior ocean. An implication of ²³⁴Th-FFs close to unity over the shelf is that particles may be retained within these sediments with little seasonal export to the interior basin. Furthermore, based on high sediment inventories of excess ²³⁴Th on the slope, this ocean margin may serve as an accumulation area for other particle-reactive chemicals, including contaminants. BIOACCUMULATION BY ZOOPLANKTON AND MICRONEMTIC FISH OF FUKUSHIMA RELEASED CESIUM AND SILVER RADIOISOTOPES IN JAPANESE COASTAL WATERS

The release of radioactive material from the damaged Fukushima Dai-ichi nuclear power plant into the ocean has raised concerns of possible radionuclide bioaccumulation in marine organisms. Here we present the first gamma analysis of biological samples collected in June 2011 as part of an international survey to Japanese waters. Bulk samples of zooplankton (>0.3mm) and micro nekton communities (~4mm) were obtained by oblique tows using Bongo and Methyl nets. Biota concentrations of the released 137Cs, 134Cs and 110mAg were compared to 40K and other natural radionuclides. 137Cs, 134Cs and 110mAg were highest for samples collected nearest to the coast, and were higher for bulk zooplankton than for microzooplankton fish, with concentrations up to 35 mBq g⁻¹ dry wt. Concentration factors of Cs in zooplankton were comparable to for other coastal fish species. The 134Cs/137Cs ratios were ~1, consistent with values reported for ratios in the plant’s effluent and ambient ocean.
surface water concentrations. Gamma radioactivity from naturally occurring radionuclides, primarily 40K, exceeded that from artificial radionuclides by about two orders of magnitude. (Abstract ID 10818)

APPLICATION OF NEW SATELLITE OCEAN COLOR DATA IN GLOBAL OCEAN MODEL SIMULATIONS

Chlorophyll highly influences the absorption of solar radiation in the upper ocean. Capturing this process in a global ocean model helps account for near-surface heating and resulting effects on vertical stability and surface heat flux. NOAA’s operational Real-Time Ocean Forecast System’s Hybrid Coordinate Ocean Model (HYCOM) and seasonal-interannual Global Ocean Data Assimilation System’s Modular Ocean Model (MOM) use monthly ocean color climatology from NASA’s Sea-viewing Wide-field of-view Sensor (SeaWiFS) to drive this process. However, NOAA’s operational SeaWiFS climatology spans only a few years and includes the major El Niño of 1998. This study explores the modeling impact of using a new ocean color climatology comprising the entire SeaWiFS record for better representativeness. Differences between the old and new datasets are significant, with the new data sets showing deeper solar radiation penetration in most coastal/littoral regions (excepting the Indonesian Throughflow region); the Antarctic Circumpolar Current region; the North Indian Ocean; and in the center of the major ocean gyres. We examine the systematic differences, focusing on mixed-layer depth, the Western Pacific warm pool region, the Pacific cold tongue, upper-ocean velocities, etc. (Abstract ID 11117)

DISSIPATION RATE AND VERTICAL MIXING INFERRED FROM SEAGLIDERS: AN APPLICATION TO THE NORDIC SEAS OVERFLOWS

Recently completed Seaglider deployments have returned nearly 18,000 full-depth hydrographic profiles around the Iceland-Faroe Ridge, resolving two of the important exchange pathways between the Nordic Seas and the North Atlantic. These observations include fine-scale vertical velocity. One Seaglider (sg005) was coordinated with a dedicated Faroe Bank Channel overflow mixing and entrainment study, which included shipboard turbulence measurements and mooring data. Here we report on a method by which dissipation rate of turbulent kinetic energy, ε, can be estimated from Seaglider vertical velocity and temperature data. Profiles of dissipation are obtained from Taylor scaling, ε ∼ q^3 l^2, where q and l are the velocity and length scales, respectively, of large eddies contributing to turbulence. We use the Seaglider vertical velocity and Thorpe displacements to define q and l. Comparison of average dissipation profiles between the cruise and sg005 determine the proportionality constant. Glider-inferred dissipation profiles capture the observed variability in turbulence, which spans four orders of magnitude within and above the energetic overflow plume. When applied to the entire Seaglider data set, regions of intense mixing and water mass transformation on the Iceland-Faroe Ridge are revealed. (Abstract ID 11171)

AGUILHAS LEAKAGE, SOUTHERN HEMISPHERE WESTERLIES, AND CLIMATE CHANGE

The Agulhas Current and its leakage of warm, saline waters between the Indian and Atlantic Oceans forms an important component of the global thermohaline circulation. Evidence from observational, palaeoceanographic, and modelling studies suggest that the Agulhas System may be a trigger or feedback mechanism for past and present climate change. Presently, a warming trend in the Agulhas System, accompanied by an increase in eddy kinetic energy indicative of more Agulhas Rings, points to increased leakage since the 1980s. Hindcast simulations which resolve the mesoscale features of the Agulhas System suggest an increase in Leakage of order 1 Sv per decade, related to the southward shift of the Southern Hemisphere westerly winds with anthropogenic climate change. An increase in leakage, combined with increased upwelling in the Southern Ocean, could potentially lead to a significant strengthening of the Atlantic overturning circulation (AMOC). This is a profound finding, since it represents a plausible mechanism to stabilise the AMOC at a time when IPCC models which do not resolve Agulhas Leakage, predict a weakening. (Abstract ID 11734)

US-JAPAN COLLABORATIVE RESEARCH ON THE MARCH 11, 2011 EARTHQUAKE, TSUNAMI INUNDATION AND INITIAL SPREAD OF FUKUSHIMA RADIONUCLIDES INTO THE PACIFIC OCEAN

A team of US and Japanese investigators has developed a high-resolution global-Japan coastal coupled WRF/FVCOM system to simulate the March 11 M9 earthquake, tsunami wave generation, propagation, coastal inundation along northern Honshu Island, and initial spread of Fukushima Dai-ichi Cs-137 across the shelf to deeper water. The Japan coastal model includes the earthquake generation zone with finer grid resolution over the inner shelf and inundation zone (down to 5 m below Fukushima Dai-ichi), with boundary and surface forcing provided by the global WRF/FVCOM. The model hindcasts will start with the initial March 11 earthquake bottom movement (provided by three advanced seismic models) through mid-April. During this period, Cs-137 source concentration levels have peaked and decreased towards increasing coastal and offshore concentration levels, indicative of cross-shelf transport and shelf-break exchange processes, with a potential sedimentation loss and biological accumulation in the nearshore region. Initial model comparisons of simulated water level with coastal tide gauge and inundation extent data show good agreement. The model system will be described and preliminary results presented. ON THE GLOBAL DISTRIBUTION OF HYDROTHERMAL VENT FIELDS: ONE DECADE LATER

Since the last global compilation one decade ago, the known number of active submarine hydrothermal vent fields has almost doubled. At the end of 2009, a total of 518 active vent fields was catalogued, with about half (245) visually confirmed and others (273) inferred active at the seafloor. About half (52%) of these vent fields are at mid-ocean ridges, 25% at volcanic arcs, 21% at back-arc spreading centers, and 2% at intra-plate volcanoes and other settings. One third (34%) are in high seas, and the nations with the most known active vent fields within EEZs are Tonga (12%), USA (combined EEZ 7%), and Japan and New Zealand each at about 5%. The range of known high-temperature, black smoker vents has extended in depth from shallowest (346 m) to deepest (3000 m) in latitude from northernmost (75N) to southernmost (60S), in temperature (to 407°C), and to ultrashallow spreading ridges. The increase in known vent fields reflects a number of factors, including systematic surveys aided by developments in technology and increased national and commercial interests in seafloor hydrothermal deposits as mineral resources. INFERRING THE GLOBAL DISTRIBUTION OF MARINE DISSOLVED ORGANIC RADIOCARBON

The published body of bulk radiocarbon (Δ14C) values has been critical to understanding marine dissolved organic carbon (DOC) biogeochemistry, yet remains significantly limited in spatiotemporal range and resolution. However, application of a simple, water-volume based mixing model to concurrent depth profiles of DOC and dissolved inorganic carbon (DIC) concentrations and Δ14C values from the Atlantic, Pacific, and Southern Oceans revealed a single, globally consistent mixing line throughout mesopelagic and bathypelagic waters. This result suggests that one (the dominant controls on DOC redistribution differ sharply between these depth horizons and the epipelagic, and (2) the global pattern of DOC Δ14C values may be predicted throughout the water column when implementing the mixing line with contemporaneous measurements of DIC concentrations, DIC Δ14C values, DOC concentrations, and simple Keeling-plots. Additional bulk DOC Δ14C observations are needed to validate the mixing line’s spatiotemporal applicability. (Abstract ID 12193)

CHARACTERIZATION AND LABILITY OF DISSOLVED ORGANIC MATTER PRODUCED BY MARINE PHYTOPLANKTON: LINKING BIOLOGICAL AND CHEMICAL DIVERSITY

Extracellular release of fixed carbon from marine phytoplankton is a major source of oceanic dissolved organic matter (DOM). If phytoplankton produce and release DOM of varying composition, DOM may impact marine biodiversity by acting as a limiting nutrient and heterotrophic community structure. To examine extracellular release of DOM by phytoplankton with an emphasis on how species diversity influences the composition of DOM, we characterized and compared organic material released by various marine phytoplankton in culture. DOM from axenic phytoplankton cultures (Prochlorococcus marinus, Synechococcus sp., Phaeodactylum tricornutum, etc.) was captured by solid-phase extraction and analyzed using mass spectrometry. We found that while a small fraction of the DOM released was common to all isolates tested, the majority was specific to individual strains or groups, suggesting a relationship between phytoplankton species and DOM composition. Phytoplankton-derived DOM suites were also given to axenic cultures of heterotrophic bacteria, and DOM additions resulted in increased growth rate and cell abundance for particular bacteria, further implicating DOM as a potential driver of marine microbial biodiversity. WATER LEVEL EFFECTS ON WAVE-DRIVEN INUNDATION: MARSHALL ISLANDS

The Republic of the Marshall Islands (RMI), two parallel island chains consisting of 29 atolls and 5 mid-ocean reef islands, lies in a region of large tidal range and energetic wave activity, and destructive inundation events occur frequently. From 2009-2011, a field experiment designed to assess water level effects on wave-driven inundation at reef protected shorelines was carried out at Majuro, the most densely populated atoll and Roi Namur at the Kwaialien atoll. Wave-driven contributions to high coastal water level events are due to wave setup, and wind wave and infragravity runup. Wave setup is controlled by breaking waves at the reef edge, and differences observed between setup estimated at the two sites may be understood in terms of a tidally dependent similarity parameter. Energy in the wind wave bound on the reef flat is highly correlated with total water level (setup and tide), with significant wind wave energy reaching the shore owing to narrow (<200-300 m) reef widths and moderate frictional decay. The dynamics of the observed infragravity motions on the reef flat also are assessed. (Abstract ID 10748)

DEVELOPMENT OF AN ANION-EXCHANGE TECHNIQUE FOR IN-SITU HIGH PRESSURE LIQUID CHROMATOGRAPHY MEASUREMENTS OF MAJOR ANIONS IN MARINE WATERS

Anion-exchange chromatography is an indispensable bench top method for anion analysis, but a high pressure liquid chromatography (HPLC) system designed for in-situ quantification of anion concentrations in marine environments does not currently exist. In-situ measurements of anions in marine environments could elucidate estuarine mixing and nutrient dynamics, allow for the acquisition of high-resolution nitrogen and sulfur redox profiles in sediments, and provide insight into geochemical processes at hydrothermal vents. A new anion-exchange technique was optimized for in-situ measurements of major anions in marine waters: the method is isocratic, eliminates the need for chemical suppression, and separates Cl-, SO4-2-, NO3-, and NO2- rapidly enough to resolve most dynamic processes. A few microliters of seawater are injected onto a commercially available anion-exchange column and ultraviolet absorbance at 214 nm is measured in the effluent. At this wavelength, the UV-active anions (Br-, NO3-, NO2-, ΣH2S) display positive peaks, while UV-inactive anions (Cl- and SO4-2-) suppress the background absorbance of the eluent and generate negative chromatographic peaks. Preliminary data obtained with this technique adapted to an in-situ HPLC developed in parallel for both benthic chamber and sediment profile measurements are presented. (Abstract ID 12268)

PHYSICAL OCEANOGRAPHY IN CUMBERLAND SOUND: AN IMPORTANT OTN STUDY SITE

As part of the Arctic OTN arena, one of the first systematic oceanographic measurement programs was conducted in Cumberland Sound, Barfin Island, over the summer of 2011. Large, remote and not fully charted, Cumberland Sound has an irregular rocky bottom with deep pools extending past 1100 m separated by sub-surface ridges 200 m deep. A temperature minimum around 150 m of -1.5 °C extends over the sound. Temperature minima like this are found in other arctic locations, potentially forming at the surface during ice cover and sinking throughout the summer. Below the water gradually warms reaching bottom values of 3 °C. Salinity increases with depth, rapidly changing in the top mixed region, with less change in the area of the temperature minimum. Density is stable with no evidence of overturns and the water column is oxygenated to the bottom of the deeper pools. Preliminary results based on summer 2011 CTD sampling and a month-long mooring deployment as well as thermistors recovered from bottom moorings set over 2010-2011, will be discussed, including possible effects on fish and mammal behavior in the sound. PHYSICAL TRANSPORT AND CHEMICAL BEHAVIOR OF DISPERSED OIL: STATE OF KNOWLEDGE AND RESEARCH NEEDS RELATED TO FUTURE OIL SPILL RESPONSE

During response operations, scientific information is provided to decision makers, such as the Federal On-Scene Coordinator (FOSC), state and federal trustees, and the public. The decision to use chemical dispersants during a response is made among all these parties, and during the Deepwater Horizon (DWH) oil spill the dispersant discussion included both surface and subsurface implication of chemical dispersants. This presentation is intended to provide perspective on operational modeling and analysis during response, and research needs related to response modeling for decision support of dispersant application and its potential effects. The presentation information is based on historical perspective, modeling and analysis results during the responses to the IXTOC 1 and Deepwater Horizon well blowout, and results from a workshop sponsored by NOAA Office of Response and Restoration and the University of New Hampshire Coastal Research Response Center, “The Future of Dispersant Use in Spill Response” held on September 20-22, 2011 in Mobile, Alabama. Our goal is to connect operational needs with the academic community. (Abstract ID 11496)

MULTIPLE APPROACHES TO ELUCIDATE THE MIGRATION OF THE AMERICAN EEL (ANGUILLA ROSTRATA) FROM THE ST.-LAWRENCE RIVER TO THE SARGASSO SEA

Although listed as special concern in Canada, estuarine and oceanic migrations that characterize the American eel’s life cycle remain largely unknown. This project aims to establish the migration routes taken by adult eels from the St. Lawrence River to the spawning area as well as to identify the dominant conditions that prevail along these routes. A system-wide effort to capture and acoustically tag individuals was conducted in 2010 and 2011. Acoustic hydrophones were deployed from the upper St. Lawrence River to Cabot Strait and the Atlantic Ocean. 18 eels are to be fitted with archival tags in a first attempt to track their horizontal and vertical migrations towards the spawning site in the Sargasso Sea. The first and second year of acoustic tracking generated novel and interesting data that are discussed in this presentation. Also, through the use of POKM (Platform for Ocean Knowledge Management), a web-based tool that allows OTN researchers conduct joint analyses of oceanographic and animal tracking data, models are being developed to examine the oceanic phase of eel migration patterns. (Abstract ID 10266)
HOW IMPORTANT ARE MESOSCALE EDDIES IN DETERMINING THE SUelpOLAR DEEPWATER FORMATION, FRESHWATER DISTRIBUTION AND AMOC RESPONSE IN GREENLAND MELTING SCENARIOS?

The role of mesoscale eddies in the oceanic response to Greenland melting scenarios is studied with a sequence of global ocean-sea-ice model simulations with increasing horizontal resolution: the models, from non-eddying ~30 km, to eddy-permitting ~15 km, up to ~3 km mesh sizes in the subarctic Atlantic, are part of developments in the DRAKAR collaboration, building on NEMO. The highest-resolution case uses a two-way nesting scheme of a 1/20°-North Atlantic domain embedded in a global 1/4°-configuration (ORCA025). Hindcast simulations using CORE forcing for 1948-2007 are shown to capture key features of the boundary currents, eddy fields and deep winter convection in the Labrador and Nordic Seas. The host of model configurations was used to simulate a Greenland melting scenario (with additional runoff of 100 mSv, equally distributed and constant in time): results show that the cross-shelf flux of meltwater is strongly dependent on model resolution, suggesting an important impact of the eddy-driven exchanges with the interior basins for convection intensity, with implications for the response of the subpolar gyre and the AMOC in honing scenarios. (Abstract ID 10254)

OTHER TOPICS OF INTEREST:

How important are mesoscale eddies in determining the subpolar deepwater formation, freshwater distribution and AMOC response in Greenland melting scenarios? The role of mesoscale eddies in the oceanic response to Greenland melting scenarios is studied with a sequence of global ocean-sea-ice model simulations with increasing horizontal resolution: the models, from non-eddying ~30 km, to eddy-permitting ~15 km, up to ~3 km mesh sizes in the subarctic Atlantic, are part of developments in the DRAKAR collaboration, building on NEMO. (Abstract ID 10254)

Mesoscale eddies play a crucial role in the oceanic response to greenhouse gas-induced warming. They are key components in the climate system, influencing heat and freshwater transport, as well as carbon and nutrient distributions. The COMPARISON OF HIGH TO LOW LATITUDE PROXY RECONSTRUCTIONS OF DEEPWATER FORMATION, FRESHWATER DISTRIBUTION AND AMOC RESPONSE IN GREENLAND MELTING SCENARIOS explains the importance of mesoscale eddies in determining the subpolar deepwater formation, freshwater distribution and AMOC response in Greenland melting scenarios. The role of mesoscale eddies in the oceanic response to Greenland melting scenarios is studied with a sequence of global ocean-sea-ice model simulations with increasing horizontal resolution: the models, from non-eddying ~30 km, to eddy-permitting ~15 km, up to ~3 km mesh sizes in the subarctic Atlantic, are part of developments in the DRAKAR collaboration, building on NEMO. “telepresence” technology that enables 24/7 world-wide real time access to the at-sea team collecting data by the ship's remotely operated vehicles. We have formed partnerships with a wide-range of educational organizations to capitalize on interest sparked by this live access: through live internet-based coverage of expeditions, formal and informal learning programs, internships, undergraduate and graduate programs, and professional development programs. The website www.NautilusLive.org provides live access to hundreds of thousands of viewers in the form of live video and audio from sea, blogs, social networking, and real-time interactions with scientists through video and audio broadcasts. The essential element to all of these programs is to engage and inspire children by giving them a compelling view of scientists and engineers as they are making real time discoveries, and to show kids the path to putting themselves on a future ship of exploration. NEW FRONTIERS IN OCEAN EXPLORATION: THE 2010 AND 2011 E/V NAUTILUS FIELD SEASONS

The Exploration Vessel NAUTILUS is creating a focus of international leadership for the development and integration of leading-edge technologies, educational programs, field operations, and public outreach programs for ocean exploration, in partnership with NOAA, National Geographic Society, Office of Naval Research, Sea Research Foundation and other sponsors. To do so, the program uses a complement of deep submergence vehicle systems and telepresence technologies to engage scientists, educators and the public, both at sea and ashore, allowing them to become integral members of the on-board expedition team. Two four-month field seasons were undertaken aboard NAUTILUS (2010-2011) to the Black, Aegean and Mediterranean Seas, and North Atlantic Ocean. During these expeditions, a number of archaeological, biological and geological discoveries were made while broadcasting the events live on the internet to thousands of viewers. When discoveries are made, experts advise are notified and brought aboard virtually within a short period of time to help guide shipboard response before the ship moves on. Future expeditions will expand our network of “Doctors on Call” to engage the widest scientific audience possible. (Abstract ID 11432)

DYNAMICS IN MARINE ECOSYSTEMS

Specifying effective ecosystem-based management strategies requires an understanding of the status, trends and interactions among key ecosystem components. Fisheries independent surveys sample major portions of marine systems and can be considered a proxy for many of the important ecosystem components. They also provide a means to compare upper trophic levels across large marine ecosystems. We quantified the potential mechanisms which drive changes in biomass among diet based functional groups with a linear, multispecies Gompertz model. Using a trawl survey database representing a number of large marine ecosystems from around the world we were able to parse out changes in biomass due to density-dependence, interactions between functional groups, fishing pressure and climate change. Through our analysis we hope to provide insight into the general ecological organization of marine systems that would enhance ecosystem-based management. (Abstract ID 12599)

SUB-TROPICAL MODE WATER SPATIAL AND TEMPORAL NUTRIENT VARIABILITY FROM DATA COLLECTED BY THE BERMUDA ATLANTIC TIME-SERIES STUDY

Determination of nutrient concentrations through the water column has been a core measurement at the Bermuda Atlantic Time-series Station (BATS) since inception in 1988. The debate about mechanisms of new nutrient input into the euphotic zone calls for further study into the variability of nutrients in the sub-tropical mode water (STMW). Winter mixing at the BATS site typically extends into this STMW nutrient reservoir which represents the dominant mode of transport of nutrients to the euphotic zone. Here we examine data from the BATS site and BATS validation cruises (travels from north of Bermuda to Puerto Rico) to detail the temporal and spatial variability of nutrients in STMW. The analyses reveal substantial variability in the STMW nutrient concentrations with long-term means at BATS of 3.76±1.54 umolkg-1 and 0.17±0.11 umolkg-1 for nitrate and phosphate, respectively and further, less than 30% of this variance is associated with conservative processes. On consideration of pre-conditioning of the nutrient pool available for the spring bloom, we assess the contribution of STMW nutrient concentrations to interannual variability of upper ocean biogeochemistry at BATS. (Abstract ID 10334)

OCEAN SCIENCE IN A CROWDED WORLD

The ocean sciences are in the midst of a revolution of both capability and motivation. Developments in marine robotics, batteries, energy scavenging technology, sensors, and the information sciences are converging to enable a permanent presence in the ocean by our robotic proxies. These technological advances, coupled with increasing global population and industrialization of the developing world, create an impetus for exploitation of ocean resources. The oil and gas industry has a large and growing presence in the ocean. Deep ocean mining is comparatively immature, but is poised for expansion. Fishing of wild species is rapidly being overshadowed by aquaculture. Other industrial activities in the ocean range from wind and wave energy conversion to proposed carbon sequestration. Thus while future ocean scientists will have unprecedented observational capabilities compared to today, they will share an increasingly crowded ocean with a range of commercial activities. Consequently, the ocean infrastructure of 2030 will need to provide observations to baseline ocean conditions and to unambiguously characterize human impacts. Ocean scientists in 2030 will need to be able to relate those observations to specific human activities. Without such a capability, policy makers will be unable to balance the demand for resource extraction with our dependence on the health of the ocean. (Abstract ID 12834)

MICROBIAL NITROGEN, CARBON, AND SULFUR CYCLING IN THE EASTERN TROPICAL NORTH PACIFIC OXYGEN MINIMUM ZONE

Oxygen minimum zones (OMZs) are biogeochemically-important regions of the ocean that are expanding as a consequence of climate change. Microorganisms directly and indirectly create OMZs, and their activities have enormous influence on global elemental cycles—however it is unclear exactly how nitrogen (N), carbon (C), and sulfur (S) are cycled in OMZs, and how different components of these cycles fit together. Here we report multiple forms of N/C/S metabolism in the OMZ of the eastern tropical North Pacific (ETNP), based on molecular techniques and rate measurements, many of these processes were coupled at different depths and in different regions of the ETNP, and we highlight coupling between ammonia oxidation, nitrite oxidation, conventional denitrification, anammox, and chemosulfatrophic denitrification. Chemosulfatrophic processes were prevalent in much of the ETNP suggesting that carbon fixation through chemosynthesis is significant, though not substantial. The communities involved were similar to, but distinct from, those in eastern tropical South Pacific (ETSP)—indicating that the ETNP and ETSP differ in important ways, and highlighting the biogeochemical complexity found both within and across oceanic OMZs. USING SELF-ORGANIZING MAPS TO IDENTIFY PHYTOPLANKTON GROUPS FROM REMOTELY SENSED DATA IN CASE 1 WATERS

Ocean color sensors have changed our vision of the marine biomass, providing frequent synoptic-scale information which allows to deduce important bio-optical parameters. A major task is to detect phytoplankton groups which is of great importance for ocean biogeochemical cycles study. Some empirical methods have been developed during the past years to detect these groups, such as “PHYSAT” which is based on anomalies of normalized water leaving radiiances (NwL), associated empirically with dominant groups (Alvain et al., 2005 and 2008). To improve this method and detect systematically the NwL*, we used a nonlinear statistical method, the so-called self-organizing maps (SOM). Associated with a hierarchical ascendant classification, SOM allowed to discriminate seven classes of NwL* using SeaWIFS images. In order to attribute a phytoplankton type to each of the spectra classes, we used SOM to classify pigments groups from a large in situ dataset, that were then matched to the NwL* spectra classes. Thus, global maps of phytoplankton groups obtained with this neural networks approach were analyzed. (Abstract ID 11828)
Diatoms play an integral role in the nitrogen cycle, and individual species differ in their physiological responses to nitrogen source and to nitrogen limitation. To identify responses to nitrogen availability common among different species and genera, we examined whole-cell transcriptomics of three evolutionarily diverse diatoms (Thalassiosira pseudonana, Pseudo-nitzschia multiseries and Fragilariopsis cylindrus). Cultures were harvested under nutrient replete, nitrate-starved and silicic acid-starved conditions, and SOLID high-throughput sequencing was used to provide a transcriptional snapshot of the metabolic response of each diatom at time of harvest. Significantly up- and down-regulated genes were identified in each species that only responded to the onset of nitrate-starvation relative to the other two treatments. The corresponding proteins included nutrient transporters and metal ion-binding proteins. These gene subsets were then compared among the three species, as well as within existing diatom EST and tiling array databases to determine whether a shared, transcriptional response to nitrogen-starvation could be detected among distantly related species. Our goal is to identify a pool of shared genes, which can then be used to interrogate field samples of diverse diatom assemblages. (Abstract ID 12715)

LONG-TERM EFFECT OF HIGH CO2 LEVELS ON CALCIFICATION AND PHOTOSYNTHESIS IN EMINIADIA HUXLEYI

The coccolithophore Emiliania huxleyi plays an important role in the marine carbon cycle through production of organic matter and calcium carbonate. Several studies have examined acclimation of E. huxleyi to high CO2, but most studies to date have mostly been short-term. To investigate the long-term response of E. huxleyi to high CO2 and elevated temperatures, we grow E. huxleyi (strain CCMP 371) in continuous cultures at 800 ppm and 24 C and at 380 ppm and 20 C as a control. Primary productivity, calcification rate as well as carbonic anhydrase (CA) expression were measured after 400 generations. Increases in calcification rate and CA expression, but not primary productivity were observed after 400 generations in the high CO2, high temperature treatment. Thus, in the future warmer and higher CO2 oceans E. huxleyi might convert more CO2 into bicarbonate via CA to use for calcification rather than use that CO2 for photosynthesis. The opposite would have been expected given that E. huxleyi has high Kc values for photosynthesis and is known to be not carbon saturated under present CO2 condition. (Abstract ID 10826)

TRACING TERRIGENOUS DOC INPUTS TO THE SOUTHEASTERN BEAUFORT SEA

Permafrost thawing and increased river runoff are expected to increase export of terrigenous DOC (tDOC) from the Mackenzie River to the Southeastern Beaufort Sea. The resulting impacts on carbon dynamics in the region are complex but inevitably depend on whether the exported tDOC lingers on the continental shelf or gets rapidly transported to the Canadian Basin. Having the ability to spatially trace tDOC inputs to the Beaufort Sea would therefore prove valuable for monitoring future changes in the biogeochemistry of this sensitive region. We present new capabilities to trace tDOC in surface waters on synoptic scales of relevance to biogeochemical cycles of Arctic ocean margins. This novel approach makes use of the spectral slope coefficient of CDOM (S370,350) as a tracer of tDOC (see related paper by Fichot and Bennett in Session 031). Here it is adapted using data collected during the MALINA project and is implemented in the region of the Beaufort Sea influenced by the Mackenzie River. (Abstract ID 11687)

FROM ESTUARIES TO OCEANS: A MULTI-DISCIPLINARY ASSESSMENT OF THE MOVEMENTS AND MIGRATIONS OF AN ENDEMIC FISH SPECIES IN SOUTH AFRICA

White steenbras Lithognathus lithognathus (Pisces: Sparidae) is one of South Africa's most threatened endemic fishery species. This study combined acoustic telemetry, conventional dart tagging, environmental data, population genetics and fishery data to enhance our understanding of the species' life history. Acoustic telemetry showed extreme residency of white steenbras within and dependence on estuarine nursery areas as early juveniles, after which they lose their estuarine-dependence and become resident within surf-zone habitats. Genetic analyses across the distributional range indicated a single, well-mixed population, and seasonal catch data suggest an annual spawning migration. However, this was not reflected by conventional dart tagging. Consequently, the existence of a seasonal annual spawning migration remains unconfirmed. The development of a national acoustic telemetry platform, including initiatives such as the Ocean Tracking Network and the collection of physical oceanographic data will allow improved assessment of longshore movements and migratory patterns of white steenbras and other marine animals, through the integration of oceanographic and animal movement data. The multi-technique approach will provide an improved scientific basis for the management and conservation of numerous marine species. (Abstract ID 9423)

THE CARBON BIOGEOCHEMISTRY OF A DISPERSING HYDROTHERMAL PLUME FROM AN ULTRAMAFIC INFLUENCED SYSTEM ON THE MID-CAYMAN RISE

Deep-sea ultramafic-hosted hydrothermal systems represent an ideal geological environment for abiotic synthesis of organic carbon and it has been proposed that early life may have begun at such systems. In modern-day oceans, ultramafic-hosted hydrothermal circulation should provide an important energy source to heterotrophic microbial communities within the crust and around vent ecosystems. However, very few studies have investigated the potential impact of abiotically produced organics on the biota that exists directly around the vents or within the dispersing hydrothermal plumes. During August 2011, a telepresence-enabled Ocean Exploration cruise on board the NOAA ship Okeanos Explorer provided us with the opportunity to investigate an ultramafic influenced system, at ~2900 m on the Mid-Cayman Rise. The hydrothermal plume above the Von Damm vent site was detected and then traced as it dispersed 4 km away from its source. Here we report on the detection of thermal anomalies and elevated concentrations of methane, together with organic carbon content and cell counts within this dispersing plume. We will discuss the potential that abiotic organic synthesis not only influences biological communities on a local scale, but also further afield, as an energy source to both auto- and heterotrophic microbial communities within the water column. HOW DO THE LAURENTIAN GREAT LAKES WATER LEVELS RESPOND TO CLIMATE CHANGE? A REGIONAL CLIMATE MODEL STUDY

The Laurentian Great Lakes contain twenty percent of the world's surface freshwater. Over the past century, inter-annual water levels have fluctuated in a primarily cyclic pattern with amplitudes from 0.2 m in Lake Superior to 0.7 m in Lake Erie. These changes in water levels result in more significant changes in coastlines of the Great Lakes and alter shoreline erosion, pollutant concentrations, and shoreline habitat. As climate changes, we are interested in how lake levels will respond. Global scale climate models do not depict the Great Lakes, and thus, are unlikely to accurately capture the mechanisms impacting water levels. We utilize the Abdus Salam International Centre for Theoretical Physics Regional Climate Model 4 at 20 km horizontal resolution with an explicit lake model, a groundwater module, and a channel routing module to simulate the past regional climate (1970-present), Nino4, and evaluate modeled climate and water levels. We then simulate present and future water levels using boundary conditions from the global Community Climate System Model. Model evaluation and preliminary findings for future water levels will be presented. (Abstract ID 10438)

MIXING, BOTTOM FRICTION, AND THE VERTICAL STRUCTURE SURF ZONE FLOWS

The surf zone and inner shell compartment off the ocean make up an important segment in the full cross-shore chain that allows exchanges between land and the open ocean. Starting from a coupled numerical model of this nearshore area (Bennis and al, 2011) we find that the cross-shore flow patterns can be extremely different when using different parameterizations for the bottom stress in association with a modified k-epsilon parametrization (Walstra et al, 2000). These differences are small for an all-shore-long uniform beach, but they are important for three-dimensional configurations (e.g. Yu and Slim, 2003). Essentially, a stronger bottom friction results in a stronger vertical mixing, which can suppress the vertical shear in the quasi-Eulerian velocity. The choice of the bottom friction parameterization thus appears critical, and some of the existing parameterizations are better suited to the inside or the outside of the surf zone. We thus implement the parameterization of waves as a source of TKE (Mellor 2002) for the modelling of wave effects in a phase-averaged bottom boundary layer, and evaluate its adequacy in the surf zone where turbulence is also provided by breaking waves. This is done on a plane beach and on a barred beach. The influence of mixing is studied on both Eulerian and Lagrangian flows. This approach provides a promising way of modelling both friction and vertical mixing in a consistent way, which is valid both in the surf zone and over the inner shell. (Abstract ID 11520)

ASSESSING BIOGEOCHEMICAL MODELS WITH HIGH-RESOLUTION AIRBORNE OBSERVATIONS OF THE O2/N2 RATIO OVER THE SOUTHERN OCEAN

The HIPPO (HIAPER Pole to Pole Observations) global airborne campaign ran five month-long deployments between January 2009 and September 2011. Deployments followed a path along the central Pacific Ocean from 10N to 67S, profiling the atmosphere from the ocean's surface to 15km, measuring, amongst other species, many carbon cycle tracers. Data from two instruments we flew on HIPPO global – the MEDUSA whole-air sampler and the AO2 vacuum ultraviolet oxygen analyzer – and compare these with output from atmospheric transport models forced by dissolved gas climatologies and a suite of ocean biogeochemistry models. FLUVIAL SEDIMENT FLUX DURING HIGH DISCHARGE EVENTS HARNESING MISSISSIPPI RIVER SEDIMENT TO BUILD NEW LAND ON AN ENDANGERED COAST

During May-June 2011, enormous fluxes of sediment were delivered to the Louisiana coast by the Mississippi River, where river stages locally exceeded records set by the Great Flood of 1927. Considering the importance of Mississippi sediment to future development of large river diversions for land building in the Mississippi Delta, we undertook a first-ever study of sediment flux, dispersal, and deposition through one of the largest man-made river diversions on the Mississippi, the Bonnet Carre Spillway. Sediment flux was monitored and sediment cores collected before and after spillway operations in Lake Pontchartrain, the estuarine spillway receiving basin. Cores were examined using Pb-210 and Be-7 geochronology, X-radiography, and granometry. Initial results conservatively suggest that spillway sediment flux during May-June was on the order of 3-4.5 Mt, of which much was deposited in a shallow-water delta building near the spillway outlet. This is comparable to fluxes that have built and are building unmanaged subdelta lobes in the modern Mississippi Delta, suggesting that pulsed delivery of sediment during high discharge events is an effective means to manage river flow for land building. SEDIMENTATION AND BIOGEOCHEMICAL MATTER REMINERALIZATION IN THE EASTERN TROPICAL SOUTH PACIFIC (ETSP): SEDIMENT TRAP AND SEDIMENT PORE WATER FLUXES

Sediment traps (100, 200, 3700 m) were used to constrain fluxes of mass, POC, PON, bSi and CaCO3 through the water column during two cruises to the ETSP at six stations located between 105 to 20S and 85W to 100W. Floating traps were deployed for 30-60 hour intervals and McLane traps were deployed for 14 months to capture weekly flux patterns between Jan. 2010-April 2011. Mass fluxes to floating traps attenuated between 100-200 m, with highest fluxes (150 mg/m2d) observed near the continent and lowest fluxes (20 mg/m2d) at 20S, 100W. POC fluxes to 200 m ranged from 0.2-1.2 mmol/m2d. Two deep moored traps (10 and 20S) captured a pulse of higher sedimentation between Aug.-Sept. 2010, coincident with lower SST in the equatorial region. Deep trap mass fluxes ranged 10-60 mg/m2d at 105 and 1.6 mg/m2d at 20S. We will discuss the attenuation of C, bSi and N vs. depth including floating trap data from 2010 and 2011 and demonstrate the relationship between opal rain and dissolution (determined by sediment pore water diffusive flux calculations). DYNAMIC CHANGES IN EDDY CORRELATION MEASUREMENTS OF BENTHIC OXYGEN FLUXES

Eddy correlation measurements typically give benthic oxygen fluxes with a temporal resolution down to 5 or 10 minutes. These fluxes often contain surprisingly large variations that may appear unrealistic. The source of this variability is twofold. Firstly, natural benthic oxygen fluxes are inherently highly dynamic – a fact that is not fully recognized, in part because most short-term dynamic changes are not recorded with traditional flux methods, such as sediment core and in-situ chamber measurements. These approaches typically impose static hydrodynamic conditions and rely on incubations times of several hours, for which one mean flux value is determined. Secondly, eddy correlation data are measured at some height above the seafloor, usually 5 to 30 cm, and this can lead to some variations in the derived eddy flux that reflect changes in the bottom water. This talk evaluates the assumptions implicitly made when the benthic flux is equated to the measured eddy flux. Furthermore, based on measured eddy correlation data and modeling of the turbulent transport and mixing in the bottom water, examples are given on highly dynamic fluxes and their origin. (Abstract ID 9515)

TIDAL TRANSPORT OF TOTAL MERCURY, METHYLMERCURY, AND DISSOLVED ORGANIC CARBON FROM A MANGROVE MARSH MEASURED USING CDOM FLUORESCENCE

Tidally driven fluxes of dissolved organic carbon (DOC) to the ocean accounts for 10% of the total terrestrial flux. Recent findings of high concentrations of mercury (Hg) and methylmercury (MeHg) in mangroves have raised concerns that fluxes of these species too may be large, owing to the commonly observed strong relationship between DOC and Hg species. We used the relationship with CDOM fluorescence to measure the dissolved organic carbon (DOC) and Hg fluxes to coastal waters from a mangrove-dominated estuary in Everglades National Park (Florida, USA). Fluorescent dissolved organic matter was used as a proxy for DOC, filtered total Hg, and filtered methylmercury (MeHg). The result was an estimated flux per unit area (yield) for DOC of 180 ± 12.6 g C m-2 yr-1 – in the range of previously reported values. Estimated yields of dissolved Hg species – 28 ± 4.5 ng THg m-2 yr-1 and 3.1 ± 0.4 ng MeHg m-2 yr-1 – were 5 to 100 times greater than previously published.
values for terrestrial wetlands. These results indicate mangroves can be a significant source of DOC and Hg to coastal ecosystems, and that coastal wetlands in general may represent important and unrecognized sources of DOC, Hg, and MeHg to the Gulf of Mexico (GOM) as a whole. (Abstract ID 12877)

MAJOR AUTOTROPHIC POTENTIAL IN DEEP-SEA PROKARYOTES IN THE NORTH ATLANTIC

To elucidate the significance and the key prokaryotic autotrophs responsible for dissolved inorganic carbon (DIC) fixation in the deep ocean, we targeted metabolic marker genes in meso- and bathypelagic waters in the North Atlantic. Specifically, the genes encoding archaeal acetyl-CoA carboxylase (acca) and ammonia monoxygenase-α subunit (amoA), the bacterial RuBISCO (cbmM) and dissimilatory APS reductase (apnA) were quantified using Q-PCR. Additionally, the bacterial and archael community composition was determined using T-RFLP complemented with a metagenomic approach. Vertical and latitudinal trends of gene abundances indicated an extensive genetic potential of DIC fixation. RuBISCO gene homologues were most abundant in the upper mesopelagial, reaching unity with apnA gene abundance, and decreasing with depth. The distribution of archael amoA gene abundances reflected the occurrence of distinct ammonia-utilizing archael communities, one adapted to utilize high and one adapted to use low ammonia concentrations. Acca-RuBISCO gene abundance ratios indicated a relative predominance of the 3-hydroxypropionate/hydroxybutyrate over the Calvin cycle. Our results suggest a larger potential of autotrophy in deep ocean prokaryotes than assumed hitherto. (Abstract ID 10992)

RESILIENCE OF THE SKIDAWAY RIVER ESTUARY: CAN HUMAN INDUCED ECOSYSTEM IMPAIRMENT BE REVERSED IN A WELL-MIXED SUBTROPICAL ESTUARY?

One of the longest continuous estuarine water quality monitoring programs in the Southeastern USA is the Skidaway River Monitoring Program (SRiMP). Since 1986 observations of hydrography, nutrients, heterotrophic microbial communities, phytoplankton, zooplankton, and dissolved oxygen have been measured in Skidaway River estuary (Georgia, USA). Uniquely, the SRiMP program captured a significant negative water quality trend with the system transitioning from net autotrophic to net heterotrophic conditions and dissolved oxygen concentrations approaching hypoxic levels. These trends could be quantitatively attributed to the development of Skidaway Island from a forested barrier island to golf course community. However, since 2000 when population growth rates on Skidaway Island slowed from a high of 25% in the early 1980’s to a current rate of less than 3%, water quality and plankton communities appear to be returning to pre-development levels. These observations suggest the inherent resilience of well-mixed subtropical estuarine systems to human disturbance and the ability to recover from seemingly catastrophic decline. (Abstract ID 12783)

OVERCOMING COMPLICATIONS POSED BY DEAD CELLS IN INTERPRETING FLUORESCENCE MEASUREMENTS IN NATURAL PHYTOPLANKTON ASSEMBLAGES

In vivo fluorescence of chlorophyll a is a traditional proxy for primary producer biomass, but it is well understood that chlorophyll and its breakdown products persist in dead cells and detrital material. Alternative measurements of induced/active fluorescence (e.g. F_i/F_r) have helped overcome the problem by providing information about the physiological state of photoautotrophic organisms, but recent work has demonstrated that such signals are strongly biased by the presence of dead cells (e.g. Franklin et al. 2009. Mar Ecol Prog Ser 382: 35). In order to identify and quantify dead cells, use of fluorescent cell mortality staining (with dyes such as Sytox) coupled with flow cytometry is a promising approach, but there are complications. We offer a framework for interpreting dead cell signals, with relevance to marine and freshwater systems. Work in a small freshwater ecosystem that allows year-round sampling at high frequency demonstrates the critical importance of: a) positive and negative controls for staining, b) ‘ground-truthing’ with microscopy, c) fine time series, and d) species-specific responses in terms of patterns and prevalence of dead cells. TIDE AND TIDAL CURRENT IN THE BALI STRAIT, INDONESIA

Tide and tidal current model using a Coupled Hydrodynamical-Ecological Model for Regional and Shelf Seas (COHERENS) is applied to the Bali Strait of Indonesia. The model well reproduces the four major tidal constituents, namely M_2, S_2, and O_1 tides, and their current. With its resolutions in the horizontal (500 meters) and the vertical (4 layers), the model is used to investigate a tidal front for the first time in the Bali Strait. The front detected by sea surface temperature distribution from the satellite, runs in the domain where the value of H/f (where H is the water depth in meters and f the amplitude of (M_2 + S_2) tidal current in m/s) close to the line of 6,5 showing that tidal straining plays an important role in its formation. Keywords: COHERENS, tidal front, Bali Strait, SST image (Abstract ID 9410)

RESPONSE OF THE OCEAN CARBON PUMPS TO CHANGES IN OCEAN CIRCULATION IN 21ST CENTURY CLIMATE CHANGE SIMULATIONS

Under increasing atmospheric CO2 concentrations the changing Earth’s radiative balance will influence the atmospheric and oceanic circulation. One of the consequences will be a modification of the ability of the ocean to absorb and store CO2. To a first degree of approximation the ocean’s carbon uptake can be separated between solubility-driven and biologically-driven pumps. The separate impact of the changing ocean circulation on these two pumps is still unclear though a partial compensation between opposite responses is expected. We design a suite of model experiments to quantify these responses analyzing a preindustrial steady state and an evolving state with atmospheric carbon concentrations rising according to historical (1880-2009) and projected IPCC scenarios. All experiments are carried out in CM2Me, a coarse version of one of the climate models (the GFDL CM2) used in the IPCC Fourth Assessment report. The ocean biogeochemical component is solved by the Biology-Light-Ion-Nutrients-Gas (BLING) model which allow the separation between biological and solubility contributions to dissolved inorganic carbon. COMPARATIVE COMPOSITION AND DIVERSITY OF SEDIMENT MACROFAUNA AT DEEP-SEA VENTS, SEEPS AND ORGANIC FALLS

Sediments associated with sites of hydrothermal venting, methane seepage and large organic falls such as whales, wood and plant detritus can create a network of soft-sediment habitats fueled in part by chemosynthesis. Understanding the level of species overlap and functional similarities between reducing habitats at different ecosystems is a key factor to reveal evolutionary links among these systems and manage specific areas in a scenario of anthropogenic exploration. In order to evaluate key similarities and differences in the sediment macrofauna of each system, this work generated a predictive framework for the study of
reducing sediment habitats and identified faunal overlap across ecosystems. Here we show that seep, vent and organic-fall sediments in the deep-sea are highly heterogeneous (family-level) in respect to both their geochemical and microbial processes, which reflect in a mosaic of habitats inhabited by a mixture of specialist and background fauna. Our study further suggests that reducing sediments exhibit distinct microbially assemblages at broad-scales (i.e. high beta diversity), which has important implications for the conservation of the unique genetic and ecological processes that exist in these ecosystems. THE ROLE OF CROSS-CANYON CIRCULATION IN GRAVITY CURRENTS DOWN CANYONS

The flow of dense water in a V-shaped laboratory scale canyon is investigated by using a non-hydrostatic numerical ocean model. Due to the earth's rotation, there is a secondary cross-canyon circulation superimposed on the down-canyon flow. The cross-canyon circulation affects the mixing and may accordingly affect the meridional overturning circulation. Many large scale numerical overflow studies are performed with fairly coarse resolution using hydrostatic models. The secondary circulation may in such studies be poorly represented. In the present study, the effects of under-resolving the cross-canyon circulation are also investigated. (Abstract ID 9825)

UNIFIED THEORY OF LAGRANGIAN COHESIVE STRUCTURES

We introduce a unified approach to locating key material curves that shape global mixing patterns in two-dimensional unsteady flows. SUCH key material curves are widely referred to as Lagrangian Coherent Structures (LCS). The theory is unified inasmuch as it is well-posed for the three relevant types of LCS: hyperbolic LCS (centerpieces of stretching and folding), elliptic LCS (eddy boundaries), and parabolic LCS (jet-like transport barriers). The LCS form solutions to a non-linear, non-autonomous, non-ordinary differential equation, and hence are available in a smooth, parametrized form. This is in marked contrast with earlier approaches to LCS, which relied on visually observing LCS as ridges of scalar quantities such as the FTLE or FSLE. In this talk the main elements of the newly derived theory are described, and results from applying the theory to surface ocean flows are presented. (Abstract ID 97/90)

SEAHUNT: THE INTERACTIVE HYDROGRAPHIC CRUISE TRACKING SYSTEM

The oceanographic community has an ongoing need for a comprehensive, up-to-date resource to facilitate coordination of upcoming hydrographic cruises. The CLIVAR and Carbon Hydrographic Data Office (CCHDO) SeaHunt fills this need with an interactive, web-accessible database of proposed and planned research cruises. SeaHunt performs like a semantic wiki, holding user contributed data with a separate web page dedicated to each cruise being tracked. All information about a cruise is open for editing and comments from registered users. All members of the oceanographic research community are encouraged to post information regarding their own current, planned, and recently-completed cruises to the SeaHunt website. Additionally, staff members augment cruise data and meta-information by maintaining an ongoing dialogue with principal investigators and data originators. Data is tracked from initial cruise planning to final disposition. SeaHunt is seamlessly integrated with the CCHDO which displays final data once it is public. (Abstract ID 12369)

TOWARDS A MONITORING OF JELLYFISH SWARMS USING AN EMBEDDED VISION SYSTEM IN AUVS, GLIDERS AND PROFILING FLOATS

The scyphozoan Pelagia noctiluca is a well-known organism in north-west Mediterranean for its regular proliferaions and invasions of near-shore waters, causing important damages to tourism economy and fisheries activity. It appears important to develop the tools to understand processes of swarms formation and basin-wide circulation of P. noctiluca populations. Jellywatch and SeaExplorer/Vasque (respectively regional and national French programs) aim at monitoring its geographic distribution using hydro-dynamical and physiological models, combined with in-situ detection from gliders and profiling floats. Here we present a miniaturised vision system dedicated to jellyfish detection embedded in autonomous platforms. On board image and data processing are made in near real-time, and data transferred by satellite. Different observational strategies are considered: a vertical monitoring using the SeaExplorer engine in glider mode to characterise the spatial disposition of jellyfish swarms in the water column; a surface horizontal monitoring using the glider in propulsion mode to estimate the size of swarms during their night surface drift; in fine, a semi-lagrangian monitoring using profiling floats that will drift together with the swarm, reproducing the vertical migration of the Pelagia noctiluca. TEMPORAL VARIABILITY IN THE BIOGEOCHEMICAL COMPOSITION OF MICROPLANKTON IN THE SARGASSO SEA

An archive of preserved microplankton net samples collected at monthly intervals since 1997 at the Bermuda Atlantic Time-series Study site has been subjected to elemental analysis and microscopy enumeration. Using a combination of elemental chemical analysis and cell-size and abundance data acquired using a FlowCAM, variability in microplankton biogeochemical composition has been examined. Particulate silica and calcium concentrations for all available spring and autumn (1997-2008) samples have been analysed including all 14 samples within one 12-month period (1999-2000). Average monthly particulate calcium concentrations follow a similar pattern to Foraminifera abundance, with lower average cell calcium concentrations coinciding with peaks in planktonic foraminifera abundance. Highest average biogenic silica values were measured in samples from July, although the largest variations in both particulate silica concentration and diatom abundances were seen during February and April. Although high variability (seasonal, annual and inter-annual) has already been documented in picoplankton populations and microbial pigments in near-surface waters at the BATS site, this study has revealed large temporal changes in two microplankton groups, and their role in biogeochemical cycling in the Sargasso Sea will be discussed. (Abstract ID 10210)

CONSEQUENCES OF SALINE MINE DISCHARGE ON MICROBIAL COMMUNITY STRUCTURE AND BIOGEOCHEMICAL CYCLING IN EPEHERMAL STREAMS

Ephemeral streams experience extreme seasonal and shorter temporal fluctuations in flow which result in rapidly changing environmental conditions including wetting and drying and changes in oxygen status of the sediments. In spite of the widespread occurrence of ephemeral and seasonally flowing streams in Australia, comparatively little work has been done to understand the interactions between hydrological regime and dynamics of sedimentary microbial processes in these systems. Understanding these relationships is critical to predict impact and regulate saline discharge from rapidly expanding mining and coal seam gas activities in many catchments. Relationships between the hydrological regime, benthic microbial structure and biogeochemical processes are being investigated in the Fitzroy Catchment, Australia. Results of field and laboratory experiments conducted across a range of spatial and temporal scales will be presented. Implications for regulation of timing and volumes of saline mine water discharge to ephemeral streams will be discussed. (Abstract ID 12454)
in suspended sediment during the WSRS period was 8 times higher than in pre-WSRS water. When the water column was strongly stratified, M. leidyi was patchily distributed and the occurrence of ZOOVIS was overlaid on a temperature-salinity diagram, it was clear that M. leidyi was more common in warm and low salinity water. When the water column was strongly stratified, M. leidyi tended to be more common near the pycnocline. When well mixed, M. leidyi tended to be more abundant near bottom. Horizontally, M. leidyi was more abundant in shallower depths near the middle Bay and less abundant in the deeper main channel. Furthermore, M. leidyi was patchily distributed spatially in terms of size, with –2 cm counted for each frame from ZOOVIS. Then, the data were aggregated in 2-sec bins and merged with data from the CTD. Artificial flood of about 20 days in the Hunaghe lower reaches for easing siltation in the river REGULATION SCHEME SINCE 2002 CHANGE OF THE MASS FLUX OF THE HUANGHE (YELLOW RIVER) TO THE sea. (Abstract ID 10902)

M. leidyi (~0.15mm – 2cm) were counted for each frame from ZOOVIS. An imaging system, Zooplankton Visualization and Imaging System (ZOOVIS) was deployed in Chesapeake Bay to investigate the fine scale distribution of ctenophore Mnemiopsis leidyi on July 20, 2011. Mnemiopsis leidyi (~0.15mm – 2cm) were counted for each frame from ZOOVIS. Then, the data were aggregated in 2-sec bins and merged with data from the CTD, which provided corresponding values of depth, temperature, and salinity to accompany data from the camera system. When the occurrence of M. leidyi was overlaid on a temperature-salinity diagram, it was clear that M. leidyi was more common in warm and low salinity water. When the water column was strongly stratified, M. leidyi tended to be more common near the pycnocline. When well mixed, M. leidyi tended to be more abundant near bottom. Horizontally, M. leidyi was more abundant in shallower depths near the middle Bay and less abundant in the deeper main channel. Furthermore, M. leidyi was patchily distributed spatially and patch size was ~50 m in diameter. Results provide insight on how M. leidyi responds to environmental changes and trophic interactions with other taxa. (Abstract ID 9944)

On Mytilus californianus shells: high resolution stable isotope study investigating environmental changes over the past 1000 years in Washington coastal region: high resolution stable isotope study on mytilus Californianus shells The successively deposited CaCO3 layers in mollusk shells could offer high resolution archives of past environmental conditions during mollusk’s life span. Here, we present high resolution oxygen and carbon isotope data from shells of mussel species, Mytilus californianus. Analyzed shells grew for ~10 years and were collected live in 2009 or 2010 from Tatoosh Island (TI), Washington. We also analyzed several shells, of the same species, present in archeological middens on TI. 14C dating suggests they lived ~1000 years ago. Shell carbonate samples were macerated across the annual growth bands to obtain time series transects with intra-seasonal resolution. Like previous sampling on annual scale, 818O data suggest no significant difference in variation range between modern and modern shells; the reconstructed temperature from modern shell 818O is comparable with the instrumental record from the study site. Fine scale sampling, however, shows oscillatory behavior, likely seasonal, in 818O data for both modern and modern shells. This allows us to test the fidelity of various growth models, i.e., constant or varying growth rate throughout the year. However, modern shells show lower 813C than modern shells, suggesting difference in carbon cycling between current and ancient conditions at this site. A declining trend was found only in 813C of modern shells; 813C of modern shells show larger amplitude of variation than modern shells, suggesting intensified seasonality. (Abstract ID 12556)

ARCHAEAL DIVERSITY PATTERNS IN RELATION TO HYDROCARBON SEEPAGE IN THE GULF OF MEXICO

Acoustic wispawt zones detected in seismic surveys of Mississippi Canyon (MC) 118 sediments in the Gulf of Mexico have been linked to elevated hydrocarbon and methane seepage. Gravity cores from within and outside of these wispawt zones had been grouped into geochemically defined clusters of high, moderate, and low methane seepage (Lapham et al. 2008). Here, we characterize the archaean communities in the same gravity cores by sequencing of archaean small subunit ribosomal RNA genes and methyl coenzyme reductase A genes (mcrA), diagnostic for anaerobic methane-oxidizing or methanogenic archaea. The archaean community in high activity cores consists mostly of archaea involved in the anaerobic oxidation of methane (AOAM). Intermediate cores harbor both AOAM archaea and sediment subsurface lineages, mostly MBGB archaea. Low activity cores contained primarily mcrA archaea, a ubiquitous sediment group. All cores yielded mcrA, suggesting that minority populations of methanogenic or methane-oxidizing archaea remain detectable even in sediments with low seepage. This study shows the systematic variation of distinct archaean communities during seepage evolution in the Gulf of Mexico. Monitoring changes in microbial response over time should thus be incorporated into hydrate monitoring programs. (Abstract ID 10010)

ONE YEAR IN THE GULF STREAM: HIGH-RESOLUTION MEASUREMENTS OF AIR-SEA INTERACTION FROM A SURFACE MOORING

We present a 14-month time series of surface meteorological and subsurface oceanic measurements from one mooring deployed in the Gulf Stream, off New England, during the CLIMODE experiment. The 1-minute sampling allows the detailed surface characterization of synoptic weather systems. Using the COARE bulk algorithm, estimates of air-sea fluxes of heat and momentum are given, with winter hourly values sometimes higher than 1200 W/m² and 1 N/m², respectively. Direct estimates of these fluxes from an eddy-covariance sensor on the same platform are also available for validation. Similar meteorological data from NDBC buoys are also used to compare air mass properties near and away from the SST front. Concomitant satellite data (AVHRR) indicate that SST spatial gradients are between 0.5 and 1 degree Celsius per km. Other remote sensing SST products, with lower resolution, underestimate these gradients. However, very rapid temporal changes in in-situ SST data suggest that SST gradients may be even higher than estimates from AVHRR. Subsurface temperature measurements below the surface mooring are also presented to describe the upper oceanic thermal structure near this intense SST front. (Abstract ID 11391)

Biogeography and oceanography of the Gulf of Mexico

This study has also identified and characterized the microbiology associated with wispawt zones and the adjacent non-wispawt sediments. We have applied both metagenetic and metatranscriptomic approaches to characterize the diversity and abundance of different microbial communities within the Cariaco Trench. Using metagenetic methods, we have identified a high diversity of bacterial and archaeal communities that are enriched in wispawt sediments. These communities are enriched in genes involved in hydrocarbon degradation, suggesting that these communities are adapted to thrive in the nutrient-rich environment associated with deep-sea methane seepage. We have also used metatranscriptomic methods to investigate the activity of these communities and have identified a high abundance of genes involved in hydrocarbon degradation in wispawt sediments. These results suggest that these communities are actively metabolizing hydrocarbons in the Gulf of Mexico. The comparison of baseline and post-spill sediment communities has provided the first insight into the environmental impacts of the BP spill on ecologically important processes in the Gulf of Mexico. Our results not only corroborate the critical role of hydrocarbon degradation in driving ecological processes in the Gulf of Mexico but also suggest that the wispawt zones are ecosystems that are highly sensitive to anthropogenic disturbance.

RESISTANCE TO OCEAN ACIDIFICATION IN LARVAE OF A SUBTROPICAL FISH

Many previous studies of the impact of ocean acidification (OA) on larval fishes are focused on benthic-spawning tropical species. Many of these studies have reported negative effects on larval development and growth, with reduced survival and decreased size-at-age. These studies have primarily focused on high CO2 treatments (~800ppm), which are well above the predicted increase in atmospheric CO2 concentration by the end of the century. However, the effects of OA on larval development and growth in subtropical species, which are likely to be more sensitive to changes in ocean chemistry, remain largely unknown. We have investigated the effects of OA on larval development and growth in the cobia, Rachycentron canadum, a subtropical reef-associated species that is widely harvested for food and sport fishing. We have performed experiments in which larvae were reared under high and low CO2 treatments, with the latter representing ambient conditions. We have measured a wide range of physiological and ecological endpoints, including survival, growth, and developmental rates. Our results have shown that OA has a significant impact on larval development and growth, with reduced survival and decreased size-at-age at high CO2 treatments. These results highlight the need for continued research on the effects of OA on larval development and growth in subtropical species, as these species are likely to be more sensitive to changes in ocean chemistry.
to observe the cycle of the seasonal pycnocline, which isolates EDW from the surface mixed layer during spring, summer, and fall, and to quantify the degree of mixing which may be responsible for the erosion of the subducted EDW layer during this restratification season. Elevated mixing and EDW erosion rates are found near the top of the EDW layer and are substantially larger than those found at the bottom of the layer. Assuming that vertical mixing is the dominant mechanism of EDW destruction, dependent upper bound estimates of diapycnal diffusivity ranging from $10^{4}$ to $10^{5}$ m$^2$ s$^{-1}$ are inferred using potential vorticity (PV) as a tracer. Diapycnal mixing is also inferred using CLIMODE and Line W hydrography. These mixing rates are used to estimate upper bound EDW volume destruction rates that are compared to formation and destruction rates inferred from climatological air-sea fluxes. (Abstract ID 10580)

ANALYZING THE EFFECTS OF CLIMATE CHANGE ON SEA SURFACE TEMPERATURE IN MONITORING CORAL REEF HEALTH IN THE FLORIDA KEYS USING SEA SURFACE TEMPERATURE DATA

This presentation discusses use of 4-kilometer satellite-based sea surface temperature (SST) data to monitor and assess coral reef areas of the Florida Keys. There are growing concerns about the impacts of climate change on coral reef systems throughout the world. Satellite remote sensing technology is being used for monitoring coral reef areas with the goal of understanding the climatic and oceanic changes that can lead to coral bleaching events. Elevated SST is a well-documented cause of coral bleaching events. Some coral monitoring studies have used 50 km data from the Advanced Very High Resolution Radiometer (AVHRR) to study the relationships of sea surface temperature anomalies to bleaching events. In partnership with NOAA's Office of National Marine Sanctuaries and the University of South Florida's Institute for Marine Remote Sensing, this project utilized higher resolution SST data from the Terra's Moderate Resolution Imaging Spectroradiometer (MODIS) and AVHRR. SST data for 2000-2010 was employed to compute sea surface temperature anomalies within the study area. The 4 km SST anomaly products enabled visualization of SST levels for known coral bleaching events from 2000-2010. (Abstract ID 10656)

ON THE BRAZIL CURRENT SYSTEM OFF SOUTHEAST BRAZIL (22S): TOP - BOTTOM DIRECT VELOCITY MEASUREMENTS

In this work we present recent top-bottom direct velocity measurements in the Brazil Current (BC) System off southeastern Brazil (22S). The dataset was collected during the CERES Experiment using L-ADCP CTD and Vessel Mounted (VM) ADCP profiles were obtained simultaneously. The observed profiles are in good agreement with the baroclinic numerical modeled velocities constrained by T-S observations and VM ADCP measurements. The results show the BC in the upper 500 m flowing southward, with maximum velocities of about 0.4 m/s and transport of 4 Sv. Below the BC, the Intermediate Western Boundary Current (IWBC) flows northward having a vertical extent of 700 m, maximum velocities around 0.15 ms$^{-1}$, and transport of about 3.5 Sv. The IWBC presents a skewed vertical structure that differ greatly from the typical parabolic-shaped cross-section of the surface-intensified BC. Our results corroborate the fact that the flow pattern of the BC System is mainly baroclinic: (up to 75-80%) off Southeast Brazil. (Abstract ID 11337)

TRACKING MICROBIAL CHANGES IN THE DEEP OCEAN; LESSONS LEARNED FROM THE D-ESP

The ESP is a field deployable system that combines autonomous sample collection with molecular analytical-detection functionality. Detection capabilities include nucleic acid and protein hybridization arrays, quantitative PCR, and sample preservation. This talk will focus on the accumulated experience gained by deploying the ESP in deep (>900m) water to study microbial populations in Earth’s oceanic seep and hydrothermal vent environments. Known as the Deep-ESP (D-ESP), the instrument and its attendant geochemical assay is deployed to a free-fall benthic lander, which can be repositioned using a remotely operated vehicle (ROV). The D-ESP is capable of operating as a stand-alone system or integrated within a deep-sea cable observatory network. This talk will present deployment results from multiple sites off the west coast of the U.S., including Monterey Bay, methane vents off Southern California, and Axial Seamount. Results show temporal and spatial changes in microbial populations and functional gene prevalence in relation to fluid source and water column chemistry. We will discuss some challenges in engineering design and microbiology procedure that result from placing a microbiology laboratory into the deep ocean. (Abstract ID 10914)

A ONE-DIMENSIONAL SEDIMENT-WATER COLUMN MODEL INCORPORATING RADIOISOTOPE 7BE

The Community Sediment Transport Modeling System (CSTMS), implemented within the Regional Ocean Modeling System (ROMS), couples hydrodynamics and sediment transport, and has been applied to many coastal locations. CSTMS has been used primarily to track particulate, non-reactive sediment, but has recently been modified to account for reactive particulate and dissolved matter, providing a new tool for evaluating preservation of event layers. Models that represent flood sedimentation estimate grain size patterns and deposit thicknesses and are therefore disconnected from field observations based on geochronology, notably 7Be (t1/2 = 53.3 days) which is delivered to the marine environment primarily by thalassic sediment. We address this issue by using a reactive sediment bed model to produce prototypical 7Be profiles for a seabed subjected to a range of flood inputs, resuspension events, and bioturbation rates. A one-dimensional (vertical) test case includes a non-cohesive sediment bed and multiple classes of sediment, some of which are initially labeled with 7Be. We examine changes to 7Be and grain size profiles through cycles of flood and resuspension events, and produce 7Be profiles that look reasonable. (Abstract ID 10567)

SHELF WATER SALINITY VARIABILITY: EASTERN NEWFOUNDLAND TO CAPE HATTERAS, AND POSSIBLE FRESHWATER SOURCES

Shelf water salinity, temperature, volume, and position of the shelf front along the eastern seaboard of the U.S. and Canada show large inter-annual fluctuations over the last three decades. Fresh water sources responsible for large-scale, shelf-wide spatial and temporal patterns of salinity variability have not been clearly identified. We seek to understand the role of Labrador Current (LC) transport fluctuations and pathways over and around the Tail of the Grand Banks, and through the Strait of Belle Isle (SBI), along with freshwater inputs from the Gulf of St. Lawrence onto the Canadian and U.S. continental shelves through examination of upstream LC transport variance and changes in St. Lawrence River freshwater discharge using a proxy quantity (RIVSUM). Minimum mean surface salinity and large annual sea surface salinity fluctuations on the eastern Scotian shelf strongly suggest a Gulf of St. Lawrence fresh water source. However, on inter-annual time scales, lagged correlations between RIVSUM and eastern Scotian shelf sea surface salinity, account for only 12% of salinity variance, implying a greater importance for input of low salinity Labrador shelf water through SBI. (Abstract ID 9746)

AUTONOMOUS EXPLORATION OF CARBON FLUX SEDIMENTATION IN THE TWILIGHT ZONE

The export of organic carbon below 100 m is 10 Pg C per year. Despite the need to understand the biological drivers for export and the depth dependence of carbon remineralization for carbon cycle prediction, there are scant observations of sedimentation dynamics in the upper 1000 m. The Carbon Flux Explorer (CFE) is designed to sustain high-frequency observations of particulate organic and inorganic carbon sedimentation to kilometer depths, absent of ships. A refined technique, reprogrammable and adaptive once deployed, and rely data to shore in near real time via Irudian satellite links for seasonal to years. Between Aug. 5 and Sept 14, 2011, two Carbon Flux Explorers, each gained 41 day records of the hourly variation of sedimentation at 250 m as they tracked the aging waters. We present first synthesis of results in contemporaneous hydrographic and remote sensing frameworks. (Abstract ID 10915)

A QUESTION OF SCALE: CONNECTIVITY OF PLANKTONIC COPEPOD POPULATIONS WITHIN AND BETWEEN OCEAN BASINS

Linkages among marine populations, communities, and ecosystems are defined by barriers to dispersal of various types, including ocean circulation patterns, biogeographical boundaries, and continents. Genetic markers of connectivity retain the signature of historical events and conditions, like climatic variation, geology of the ocean basins, and genetic bottlenecks, among others. For cosmopolitan open-ocean pelagic species (i.e., those found in all ocean basins between 40°N to 40°S), genetic distance may be significantly correlated with oceanographic distance (i.e., as the current flows) between collection sites. In this study, we use DNA sequence variation of the barcode region of mitochondrial cytochrome c oxidase I as a standard measure to examine and compare the relationship between ocean circulation and connectivity within and between ocean basins among diverse species of planktonic copepods. The results are evaluated in terms of morphological, ecological, biogeographical, and evolutionary characters of the species. Comparative phylogeographic analysis will be useful to understand, quantify, and predict coupled responses of communities in response to ocean circulation changes that may be driven by climate change and variability in the future. (Abstract ID 9570)

DEVELOPMENT AND EVALUATION OF OCEAN-CLIMATE MODELS: AN IMPLEMENTATION OF GM FOR UNSTRUCTURED VERTICAL GRIDS

An implementation of the Gent-McWilliams (GM) parameterization of eddy fluxes suitable for ocean models using unstructured vertical grids is presented. Owing to the intended use of this scheme in quasi-isopycnic coordinate models like HYCOM, the scheme makes use of the concept underlying GM that baroclinic instability flattens isopycnals. Laplacian interface smoothing in HYCOM, originally introduced to suppress grid-scale noise and later equipped to diagnose the resulting bolus fluxes, already captures the essence of GM in that model's isopycnic subdomain but has no effect in its level coordinate subdomain. The proposed scheme removes this incongruity by (a) transforming the model state into purely isopycnic space; (b) smoothing the resulting interfaces; (c) deducing the bolus fluxes spawned by the smoothing; (d) projecting the bolus fluxes back onto the native grid where they are then used for transport. Baroclinic channel flow experiments using different combinations of fixed-depth and isopycnic coordinates depict the expected transition from a thermally indirect Deacon cell, typically seen in level coordinates, to a thermally direct overturning pattern when the proposed GM parameterization is applied. The scheme is numerically resilient even in weakly stratified regions but is not meant to address questions regarding the proper use of GM in the surface mixed layer. (Abstract ID 12305)

OS/AGU/ASLOAbstract Book
Time series data archived from pressure, accelerometer, or thermal sensors permits analyses of diving behaviour and thermal physiology providing remarkable insights about reproductive biology. We show these migratory species exhibit incredible patterns of site fidelity and navigate specific corridors within vast seas to reach regions critical to their life history. By integrating biologging technology with oceanography, isotope studies, and molecular genetic analysis, we now have a better understanding of the lives of apex marine predators and the perils they face in the future. FOOD WEB STRUCTURE AND EPIBENTHIC MACROFAUNA IN THE CHUKCHI SEA: A COMPARISON BETWEEN 2004 AND 2009

The Russian-Americans-Long-term-Census-of-the-Arctic builds a time series of environmental and biotic conditions in the Chukchi Sea, an area experiencing substantial climate change. Here we present a first comparison of food web structure and epi-benthic communities between 2004 and 2009. In 2004, food web structure, based on 13C ratios, differed regionally with benthic organisms in the eastern Chukchi Sea experiencing more terrestrial material than those in the western part. Similar patterns were found in 2009, but the 13C depleted food source indicated freshwater influence in the western region in 2009. Based on 15N ratios, no differences in trophic position of benthic consumers were found between the two years. Epi-benthic macrofauna from 60 trawl samples, including 8 resampled stations, was dominated in abundance and biomass by echinoderms and crustaceans in both years. Species richness was highest for mollusks and crustaceans in both years. Repeat stations and comparison with earlier studies suggest an increase in overall epibenthic biomass (since 1976), including an increase of the now often dominant snow crab. Geographically, the sampling coverage was expanded to the eastern East Siberian Sea in 2009. (Abstract ID 9363)

ASSIMILATION OF HF RADAR-DERIVED SURFACE CURRENTS ON TIDAL-TIMESCALES

A surface current observation system based on high-frequency (HF) radar has been developed for Barter Island, NE, and the coastal waters of New York and New Jersey. Data from this system is being assimilated via a Newtonian damping scheme into the New York Harbor Observing and Prediction System. The impact of the HF radar data assimilation (DA) is analyzed by computing the DA skill by comparing (non-assimilated/assimilated) model solutions with in-situ observations of three-dimensional currents, temperature, and salinity which have not been included in the assimilation. The HF radar data were assimilated into the NYHOPS model hindcast cycle on daily forecast basis for a period of 49 days beginning 24 February 2007. Model skill metrics for the near-surface layers in the inner-NH shelf region show improvements of hindcast DAskill of 24% and forecast DAskill of 18% for three-dimensional u (v) currents, and a hindcast improvement DAskill of 33% and forecast DAskill of 25% for three-dimensional temperature (salinity). The nudging scheme is robust and efficient for the HF radar DA into the operational NYHOPS forecast model and is capable of importing in the observations with minimum computational expense. DIVERSE DATA SYSTEMS FOR BIODIVERSITY DATA, A CASE STUDY OF MARINE MAMMAL OBSERVER DATA

Cooperative efforts across academic, government, and industry partners can help support expansive data requirements of CMSP's integrative management framework. Professionals coordinate at the community level, for example a geophysical or an ecological society, to develop data systems for exchanging and managing common data. Data systems tend to be built around standards, like the Climate and Forecast metadata conventions for NetCDF, because this can help reduce costs and duplicative effort across the community. However, a challenge to producing nationally consistent digital data and metadata occurs when partners from the associated scientific community use specific applications that produce data heterogeneity. A case study is examined for when a specific application, marine mammal observer data, are synthesized with other data from a broader community using the US Ocean Biogeographic Information System (OBIS). OBIS functionality complements the US National Oceanographic Data Center's efforts to preserve these data for re-use by marine mammal biologists. We discuss the meaning of data standards in the context of this diverse data system and how standards help national repositories to better support CMSP. (Abstract ID 11962)

VISUAL BASIN-SCALE SURVEY OF DEEP-SEA PARTICLES (200 – 6000 M) IN THE TROPICAL AND SUBTROPICAL ATLANTIC OCEAN USING A DIGITAL IN-LINE HOLOGRAPHIC MICROSCOPE

Particles in the size range of 100 µm to 5 mm dominate the mass flux from the surface to the deep sea with smaller particles being too small to sink, and larger ones not sufficiently abundant to contribute appreciably to the flux. However, many live zooplankton organisms and neutrally buoyant particles also fall within this size range. Thus, accurate quantification of sinking flux based on particle numbers and sizes alone is difficult unless particles can be better characterized. One step towards this goal is to visually examine these particles and group them into categories of potentially sinking (e.g., dense fecal pellets, ballasted debris), free-swimming (zooplankton) and potentially neutrally buoyant (e.g., amorphous, low-density marine snow particles). Here we demonstrate the application of digital inline holographic microscopy (DIHM) for particle characterization and sizing for specific water masses such as the oxygen minimum zone, the North Atlantic Deep Water and the Antarctic Bottom Water. An important advantage of DIHM over conventional microscopy is its inherently large survey volume at high resolution. (Abstract ID 12228)

DEVELOPING REGIONAL TOOLS FOR DATA INTEGRATION

The Alaska Ocean Observing System functions as a regional oceanographic data assembly center and operates several user interface tools and backend data management systems. Developing sustainable and scalable information systems requires the integration of several disciplines including informatics, software engineering, and cyber-infrastructure design. Utilizing interoperability systems for data transport and High Performance Computing (HPC) techniques for visualization/analysis ensure that data is openly available to the broader user base in addition to other machines and data assembly centers. AOOS is developing several tools which leverage a common underlying application framework called the AOOS Ocean Portal. The AOOS Ocean Portal provides a platform to rapidly deploy tools which are specific to regions, themes, management issues and emergency response and planning applications. As a result, the AOOS data management team can actively support several independent user interface tools, each with their own subset of data and functionality, supported by a single collective code base. A specific portal is scheduled for release in January 2012 which integrates atmospheric/oceanographic models and remote sensing data sets, real time and historic sensor streams and GIS data layers for the Cook Inlet region. Several additional tools are in development including a circumpolar Arctic portal. (Abstract ID 12082)

THE IMPACTS OF CENTRAL- AND EASTERN-PACIFIC EL NINO EVENTS ON THE SOUTHERN OCEAN
El Nino is known to have significant influence on the global ocean and weather patterns. Classical El Nino events are characterized by a maximum SST anomaly in the eastern-equatorial Pacific. Since the 1990s, there have been frequent occurrences of the so-called central-Pacific El Nino, where the maximum SST anomaly is located in the central equatorial Pacific. Classical El Nino events are known to influence Southern Ocean dynamics, sea ice and heat flux through atmospheric teleconnections. In this study, we investigate the impacts of the ongoing change in El Nino characteristics on the Southern Ocean using multi-sensor satellite observations along with ECCO ocean state estimation products. We analyze Southern Ocean sea surface temperature, sea level, ocean bottom pressure anomalies, and changes in the circulation of the Southern Ocean (including the Antarctic Circumpolar Current) in general to characterize the differences of the state of the Southern Ocean during central- and eastern-Pacific El Nino events. The study also contrasts the influence of the Southern Annular Mode (SAM), the dominant mode of atmospheric variability over the Southern Ocean, to the effects of El Nino. (Abstract ID 10765)

ON THE DISPERAL OF LEATHERBACK TURTLE HATCHLINGS FROM MESO-AMERICAN NESTING BEACHES
So little is known about the early life history of leatherback turtles (Dermochelys coriacea) from hatching to adulthood that this period has been termed the “Lost Years.” For critically endangered eastern Pacific leatherback populations, continued and rapid declines underscore the urgent need to develop conservation strategies across all life stages. We investigate leatherback hatching dispersal from four Meso-American nesting beaches using passive tracer experiments within a Regional Ocean Modeling System (ROMS). The evolution of tracer distribution from each nesting beach showed the strong influence of eddy transport and coastal currents. Modeled hatching from Playa Grande, Costa Rica, were most likely to be entrained and transported offshore by large-scale eddies coincident with the peak leatherback nesting and hatching emergence period. These eddies potentially serve as “hatchling highways” providing a means of rapid offshore transport away from predation, and a productive refuge within which newly-hatched turtles can develop. We hypothesize that the most important leatherback nesting beach remaining in the eastern Pacific (Playa Grande) has been evolutionarily selected as an optimal nesting site due to favorable ocean currents that enhance hatchling survival. CHARACTERIZATION OF ORGANIC LIGANDS IN CULTURES AND SEAWATER BY HPLC-ICP-MS
Organic ligands dominate the speciation of many oceanic trace metals and have important effects on metal solubility and bioavailability. Information on the chemical composition and distribution of marine metal complexes is therefore helpful to our understanding of biogeochemical metal cycling. One approach is to extract organic ligands from seawater and identify the compounds that are associated with trace metals. We have developed a method to separate organic compounds by high-performance liquid chromatography and measure their metal content via multi-collector inductively coupled plasma mass spectrometry. The detector response increases linearly with metal concentration and varies with solvent composition (water - methanol). After concentrating organic compounds from seawater and cultures on a polystyrene resin and analyzing the extract with our method, we characterize peaks that correspond to organic-metal complexes. The fraction containing these compounds can be collected and further purified for detailed characterization by nuclear magnetic resonance spectroscopy and mass spectrometry. The method can detect less than 1 pmol of a metal complex and allows us to study ligands of multiple trace metals simultaneously, such as Mn, Fe, Co, and Ni. (Abstract ID 9464)

RAPID GLACIAL-MARINE SEDIMENTATION AND EFFECTS ON GLACIER MELTING AND FJORD HYDROGRAPHY: COLUMBIA GLACIER FJORD, AK
Marine-ending glaciers are retreating rapidly worldwide, and many recent studies point to ice-ocean interactions as some of the most important and least understood processes controlling glacier mass balance and sea-level rise. Since 1982, the rapid retreat of Columbia Glacier has exposed a 16-km-long fjord, of which very little about the marine environment is known. New bathymetric, seismic and sedimentologic measurements collected in September 2011 suggest rapid (tens of meters per year) accumulation of sediments near the glacier front. The rate of sediment accumulation is on the same order of magnitude as rates of ice surface lowering and thinning, and hence the glacial sedimentation is likely to be important to glacier stability. These deposits shield the ice front from circulating warm ocean water, and thereby slow the ice loss due to submarine melting. Seismic records, bathymetry and preserved sedimentary structures within the fjord deposits suggest gravity flows are likely to be the dominant sediment transport mechanism, which may be linked to seasonal and other changes in the subjacent hydrologic system. The sedimentary record preserved within the newly-opened fjord contains a record of glacier behavior, associated climatic changes, erosion, and sediment transfer events. (Abstract ID 10689)

ZOOPLAGNKTON COMPOSITION AND ABUNDANCE IN LAMONI BAY, NORTHEAST LUZON, PHILIPPINES
There has been a lot of interest in understanding the oceanographic and ecological dynamics occurring in the waters off northeastern Luzon, Philippines. This area is highly influenced by the western boundary current system of the western Pacific as brought about by the bifurcation of the north equatorial current into the Kuroshio and Mindanao Current. Previous studies have identified high primary productivity in several areas that are said to be driven by upwelling
dynamics near the shelf. These processes are usually linked to productive fisheries. The focus of this study then is on the link between primary productivity and fisheries, which is zooplankton and ichthyoplankton. Plankton collection was conducted along spatial zones identified a priori based on chlorophyll a profiles determined from previous studies. Quantitative and qualitative analysis was done using conventional microscopes and a FlowCAM. Data among spatial zones were then compared. (Abstract ID 12667)

SEASONAL BENTHIC NUTRITION CYCLING IN A BALTIC SEA ESTUARY

Decades of urban, industrial, and agricultural discharge of nitrogen and phosphorus to the Baltic Sea have contributed to the spreading of water column hypoxia and annual widespread cyanobacteria blooms. Central to mitigating Baltic Sea eutrophication is to resolve how much reduction strategies of external N and P loading are offset by internal loading of the Baltic through nutrient recycling from the sediment. We investigated the seasonal variation of benthic nitrogen and phosphorus cycling in an estuary of the Baltic impacted by decades of sewage discharge. Sediment nutrient fluxes, denitrification, Anamox, DNRA, potential nitritation, and total and diffusive oxygen uptake (TOU/DOU) were quantified with 15N-tracer methods and microsensor profiles. Data indicate benthic net effux of ammonium and phosphorus during the summer months, decreasing N loss with increasing organic matter content, and benthic N/P regeneration with a ratio of 3 to 7 compared to the sewage discharge N/P of 25, and a significant contribution (6 to 25%) of Anamox to N loss. On average benthic denitrification and Anamox may reduce the N load to the estuary by up to 54%. (Abstract ID 12091)

THE WIND FORCING OF NEAR-INERTIAL WAVES AT THE KUROSHIO EXTENSION OBSERVATORY (KEO) AND JAMSTEC KUROSHIO EXTENSION OBSERVATORY (JKEO)

The western North Pacific experiences a variety of storms during the cool season. These storms influence the ocean through their modulation of radiative and turbulent (sensible and latent) heat fluxes at the air-sea interface, and through wind forcing. The present study focuses on the latter mechanism, in particular the generation of near-inertial waves (NIWs) due to their influence on oceanic mixing. Storms that feature local winds rotating anti-cyclonically with time can lead to wind forcing in quasi-resonance with NIWs, hence generating large amplitude NIWs. The present study considers hourly data from the Kuroshio Extension Observatory (KEO) and JAMSTEC Kuroshio Extension Observatory (JKEO) moorings. The analysis involves computation of rotary wind spectra during the cool seasons (October-March) of 2004-2010 for KEO and 2007-2010 for JKEO. The upper ocean responses observed at KEO and JKEO to storms with strong forcing of NIW are compared with the responses to cold-air outbreaks accompanied by enhanced surface heat fluxes. The relative frequencies of these two kinds of storms on monthly to seasonal time scales are related to large-scale atmospheric circulation patterns. (Abstract ID 9594)

NEARSHORE RESOURCE CHARACTERIZATION MAPS: MARINE SPATIAL PLANNING, CAPACITY BUILDING AND COASTAL SCIENCE IN MASSACHUSETTS

An ongoing 3-year study to develop methods to produce shallow water (1-10 m), nearshore resource characterization maps for the Massachusetts Office of Coastal Zone Management is nearing completion. The project description also noted ‘the need to build capacity’ to collect these types of data at the host institution. The Provincetown Center for Coastal Studies. Toward that end, a state-of-the-art interferometric sonar system was acquired. This instrument collects coincident swath bathymetry and acoustic backscatter imagery and is designed specifically to work in nearshore environments. The impetus for this project was the need to develop high resolution, high accuracy resource maps to better manage the state’s marine resources. Scientists and managers working with these data are actively formulating unexpected directions of inquiry and investigation. As innovative technologies increase the quality of data, new ideas and fresh questions are asked, and a better understanding of the natural system is reached. Some examples include documenting seafloor features <5 cm in relief, a potential new method for remotely sensing elgrass biomass, and tide-coincident, seamless, onshore-offshore resource maps. Our understanding of the carbonate parameters from hydrographic data in the Southern Ocean has been considerably advanced by the collection of large global datasets over the last 50 years (GOSECS 1960-1970s, GLODAP 1990s, CARINA and PACIFICA 2000s). However, there are still many areas of the globe that have had little sampling for carbonate parameters. We have used the global datasets from the Southern Ocean (south of 26°S)greenS), with measured dissolved inorganic carbon (DIC) and alkalinity to develop multiple linear regressions (MLR) to estimate alkalinity and DIC from the common hydrographic parameters: temperature, salinity, depth, pressure and oxygen. We find distinct regimes based on water masses, where the alkalinity and DIC differ from the different atmospheric and oceanic processes. The aim of this work is to use all the hydrographic data for the region to produce detailed maps of the carbonate parameters: pCO2, pH (CO32-), aragonite saturation, calcite saturation, that take into account local currents, especially around complex topography e.g. around New Zealand. Oxygen sensors on Argo floats would further improve the coverage and allow for estimates of seasonal and interannual variability in carbonate parameters. (Abstract ID 10632)

**SUGGESTIONS TO HELP TEACHERS ACHIEVE MORE WHILE DOING OUTREACH**

Teachers have helped scientists disseminate marine sciences information through a number of research experience programs that place teachers in research projects. Teachers can be effective translators of a discipline’s content and research methods because they understand students’ potential and limitations. The partnership with educators is taking new meanings as teachers interact with larger communities through new technologies that allow them to write blogs and broadcast their experiences from the field. Yet, content quality still depends on the teacher’s knowledge of the field. In this presentation, we will suggest activities that will help researchers prepare teachers so that content quality can be maximized. We will also share the challenges and successes of these activities from the field. Our suggestions are based on the experience of one high school teacher with a Masters in Oceanography who spent 64 days on a cruise in the Southern Ocean (CLIVAR SfP) through PolarTREC (Teachers and Researchers Exploring and Collaborating) (Abstract ID 9462)

**INLAND SEAS**

A 10,000 km² hypoxic ‘dead zone’ forms, during most years, in the central basin of Lake Erie. To investigate the processes driving hypoxia, we conducted a two-year field campaign. Mixing in the lake interior, during the stratification period, was examined using current meter and temperature logger data as well as ~600 temperature microstructure profiles; from which turbulent mixing parameters were computed. Our results demonstrate that near-inertial Poincaré waves drive shear instability, generating ~1 m amplitude and 10 m wavelength high-frequency internal waves with ~1 m density overturns. These lead to greater than one order of turbulent mixing parameters from spectral backscattering dependence. (Abstract ID 10265)

**SECLUSIONS**

To this aim measurements were focused on one of the most energetic sections for internal waves in the Indonesian seas are one region of the strongest internal tide generation these waves significantly modify the energy flux paths relative to small and medium sized lakes where $>0.25$. (Abstract ID 11713)

**TURBULENT MIXING AND INTERNAL TIDES IN THE INDOMIX CRUISE**

The Indonesian Throughflow is the only passage at low latitude between the Pacific and the Indian oceans. As such it constitutes a key region of the thermohaline circulation where water mass properties are strongly modified as a result of a strong turbulent mixing. As the Indonesian seas are one region of the strongest internal tide generation these waves are expected to play a major role in driving this mixing. The INDOMIX cruise aimed to characterize small-scale turbulence and its relationship with the larger scale internal tidal signal. To this aim measurements were focused on one of the most energetic sections for internal tides located within the Alenghara sea area. Classical time-scale measurements have been performed together with microstructure measurements with repeated profiles over 24 hours. A strong internal tidal signal was evidenced with currents up to 50 cm/s and solitary waves leading to isopycnal displacements of the order of 50m. Consistently high values of energy fluxes up to 80kW/m were obtained with various propagation directions. The latter reveals the complex pattern of internal tide generation occurring both along the shelf edge and within passages. Spots of high energy dissipation were characterized below the pycnocline where the strongest internal tidal signal is observed as well as above the bottom topography. Eventually a set of
fine-scale parameterizations was tested against our turbulence measurements and a refined parameterization proposed. (Abstract ID 11310)

IMPACT OF NON-LINEARITIES ON AN INCREMENTAL 4D-VAR DATA ASSIMILATION METHOD IN A HIGH RESOLUTION NUMERICAL OCEAN MODEL.

A current state for numerical ocean models is to adequately represent meso- and small-scale activity, in order to simulate its crucial role in the general ocean circulation and energy budget. It is therefore also a challenge for data assimilation (DA) methods to control these scales. However this small-scale activity is strongly linked to the nonlinear character of the flow, whereas DA methods are generally much less efficient in such contexts than in (almost) linear ones. The purpose of this poster is to address this problem specifically, by exploring the behaviour of an incremental 4D-VAR DA method in a nonlinear ocean model. A series of experiments assimilating simulated altimeter data in an idealized Gulfstream-like configuration of the NEMO ocean model at increasing resolutions (which is a proxy for increasing nonlinearity) are analyzed. We present in particular results characterizing scales and structures of the analysis error along the assimilation process, as well as tentative links with small scale activity. Moreover we investigate some strategies for DA in such nonlinear contexts, with the aim of reducing this analysis error. (Abstract ID 11031)

LIGHTLY TETHERED UNMANNED UNDERWATER VEHICLE FOR UNDER-ICE EXPLORATION

The Woods Hole Oceanographic Institution has been awarded funds by the National Science Foundation to develop by 2014 a robotic underwater vehicle for under-ice exploration. By employing a long, light-weight tether, the vehicle will provide the U.S. Polar Research Community with the capability to tele-operate, under direct real-time human supervision, a remotely-controlled inspection and survey vehicle under fixed ice at ranges up to 20 km distance from a support ship. The vehicle will enable exploration and detailed examination of the biological and physical under-ice environment through the use of high-definition video, coupled to a suite of chemical and biological sensors. Conventionally-tethered ROV systems, limited to horizontal ranges of a few hundred meters from their support ships, cannot access environments under ice too thick to further. Under, long-range light-fiber tether technology provides the high bandwidth link necessary for real-time control under the direction of the shipboard science party that AUVs cannot meet. Thus, the PROV (Polar-ROV) will enable upward imaging of the ice underside, and downward imaging of the seafloor on the continental shelf to depths of 1000 m. (Abstract ID 11678)

FUNCTIONAL GENE PYROSEQUENCING: CHARACTERIZING THE DISTRIBUTION AND DIVERSITY OF THE NIRS GENE AND ITS ROLE IN DENITRIFICATION OF COASTAL MARINE SEDIMENTS

Recent advances in DNA sequencing technology have expanded efforts to understand the role of microbes in ecosystem function. Two approaches are widely used: sequencing 16S rRNA to examine the extent of taxonomic diversity, and sequencing metatranscriptomes to examine the distribution of genes being expressed. The former provides information on microbial diversity, but little on ecosystem function. The latter is informative with regard to function, but is only capable of capturing a fraction of the total number of expressed genes. We developed a hybrid approach wherein we use pyrosequencing to examine genetic diversity, but to explore the relationship between genetic diversity and ecosystem function we focus, instead, on PCR-amplicons of a single functional gene. Our proof-of-concept focuses on nirS, a key gene in the denitrification pathway, that plays a critical role in coastal systems by removing fixed nitrogen. However this small-scale activity is strongly linked to the nonlinear character of the flow, whereas DA methods are generally much less efficient in such contexts than in (almost) linear ones. The purpose of this poster is to address this problem specifically, by exploring the behaviour of an incremental 4D-VAR DA method in a nonlinear ocean model. A series of experiments assimilating simulated altimeter data in an idealized Gulfstream-like configuration of the NEMO ocean model at increasing resolutions (which is a proxy for increasing nonlinearity) are analyzed. We present in particular results characterizing scales and structures of the analysis error along the assimilation process, as well as tentative links with small scale activity. Moreover we investigate some strategies for DA in such nonlinear contexts, with the aim of reducing this analysis error. (Abstract ID 11031)

BACKSCATTERING OF LIGHT BY SUSPENDED PARTICLES

Ocean colour measurements rely on the backscattering of light. As with other optical properties, backscattering by particles is expected to be a function of particle cross sectional area, although there are few data sets that explore the relationship explicitly. Here, we report measurements of backscattering coefficients and particle cross sectional area in UK coastal water. The results show that the backscattering coefficient increases with particle area per unit volume but that the slope (the backscattering efficiency) depends on the percentage of organic material. The efficiency is about 0.01 for high organic content rising to 0.06 as organic content falls to 10%. A tentative explanation is that this is due to the higher refractive index of mineral material. The implication for remote sensing is that reflectance coefficients depend upon the mineral content as well as the area of particles in suspension. Hill et al., report in this session that the area of particles per unit mass increases with the organic content. Together, these findings may explain why ocean colour is so good for deriving the mass concentration of suspended sediment. (Abstract ID 10884)

TRENDING OF THE COASTAL "GAIN" AT DIFFERENT TIME SCALES USING TOA RADIANCE (LT/VT/L) FOR OCEAN COLOR SENSORS.

We examine time scales of variability of "gain" or bias in spectral radiance between satellite and in situ measurements from the AERONET-OC. Using a long time series of match-ups of ocean color radiance, we determined how the gain changes on weekly, monthly, and annually cycles for different global regions. This enables us to establish practicable spectral "offsets" that can be used for regional adjustment of satellite derived water leaving radiance. This is done as a preliminary step in a larger effort to expedite calibration of the VIIRS and GOCI sensors. The current procedure requires years of coincident data collection before sufficient match-ups can be obtained to produce a valid vicarious calibration. By using the match-up procedure of NASA ORBG and exploiting radiometrically calibrated data from the AERONET-OC sites, short term monitoring of the relationship between satellite derived top of the atmosphere (TOA) radiance, Lt, and in situ nLw propagated to TOA, vLt, can provide basic information to support ocean color products during the early stages of sensor deployment. DIRECT OBSERVATIONS OF FORMATION AND PROPAGATION OF SUBPOLAR EDDIES INTO THE SUBTROPICAL NORTH ATLANTIC

Subsurface float and moored observations are presented to show for the first time the formation and propagation of anticyclonic submesoscale coherent vortices that transport relatively cold, fresh subpolar water to the interior subtropical North Atlantic. Acoustically tracked RAPOS floats released in the southwest-flowing Western Boundary Current at the exit of the Labrador Sea reveal the formation of three of these eddies at the southern tip of the Grand Banks (42°N, 50°W). It was found that the eddies had average rotation periods of 5–7 days at radii of 10–25 km, with mean rotation speeds of up to 0.3 m s⁻¹. One especially long-lived (5.1 months) eddy crossed under the Gulf Stream path and translated southwestward in the subtropical recirculation to at least 35°N. Velocity, temperature and salinity measurements from a nine-month deployment of two moorings south of the Gulf Stream at 38N, 50W reveal the passage of at least two eddies with similar hydrographic and kinematic properties. The core temperature and salinity properties of the eddies imply their formation at intermediate levels of the Labrador Current south of the ‘Tail of the Grand Banks. These observations confirm earlier speculation that eddies form in this region and transport anomalously cold, low-salinity water directly into the subtropical interior. (Abstract ID 9321)

BACKSCATTERING OF LIGHT BY SUSPENDED PARTICLES

Ocean colour measurements rely on the backscattering of light. As with other optical properties, backscattering by particles is expected to be a function of particle cross sectional area, although there are few data sets that explore the relationship explicitly. Here, we report measurements of backscattering coefficients and particle cross sectional area in UK coastal water. The results show that the backscattering coefficient increases with particle area per unit volume but that the slope (the backscattering efficiency) depends on the percentage of organic material. The efficiency is about 0.01 for high organic content rising to 0.06 as organic content falls to 10%. A tentative explanation is that this is due to the higher refractive index of mineral material. The implication for remote sensing is that reflectance coefficients depend upon the mineral content as well as the area of particles in suspension. Hill et al., report in this session that the area of particles per unit mass increases with the organic content. Together, these findings may explain why ocean colour is so good for deriving the mass concentration of suspended sediment. (Abstract ID 10884)

MICRONUTRIENT TRACE ELEMENTS IN THE AUSTRALIAN SECTOR OF THE SOUTHERN OCEAN: MERIDIONAL DISTRIBUTIONS AND SEASONALITY

Southern Ocean phytoplankton growth and community composition is unquestionably limited by micronutrient trace elements, with iron playing a central role. Change in the supply and availability of iron may be the single largest forcing of Southern Ocean ecosystem productivity and health in the next century, and thus is intrinsically linked with changes in carbon cycling and global climate. The Southern Ocean sector south of Australia has seen extended efforts of sampling since 1994, most notably along the SR3 section from Antarctica to Tasmania (~140°E), with nearly 300 seasonal iron observations in surface waters. Here we present the full water column distributions of a series of trace elements along SR3 conducted as part of the GEOTRACES program, including micronutrients (Fe, Cd, Co, Cu, Ni, Zn) and tracers (Al) of sources. We examine the importance of biological activity; trace element supply (upwelling, boundary currents, dust), hydrothermalism, glacial melt, and water mass characteristics in governing the meridional and seasonal distributions, with a focus on decoupling of trace element and nutrient cycles, and the characteristics of surface water replenishment processes for springtime production. RETRIEVAL OF IOPS, BATHYMETRY, AND BOTTOM TYPE INFORMATION FROM HICO DATA

A Lookup Table approach to retrieving IOPS, bathymetry and bottom type information has been applied to HICO imagery. The LUT spectra are generated using EcoLight and uses known bottom type information. As many as one million calculated spectra span the expected range of parameters are used. The comparison metric used is the unweighted Euclidean distance. In clear water examples, such as the Bahamas, it is shown that mixed bottoms are important to consider. In particular, adding mixtures at the 10/90 or 75/25 ratios, shows improved matches between the measured and calculated spectra. The level of mixed bottoms that must be represented in the LUT is important because adding many mixtures slows the processing to unacceptable levels. As an alternative to adding spectra to the LUT, an optimal estimation step may be helpful. (Abstract ID 11404)

EVIDENCE FOR STRONG SELECTIVE ENRICHMENT OF BACTERIA WITHIN FROST FLOWERS ON THE SURFACE OF ARCTIC SEA ICE

Frost flowers, saline ice structures on the surface of newly formed sea ice, have received recent attention for their potential role in atmospheric halogen chemistry and aerosol production and their newfound habitability. We analyzed bacterial community composition and structure (16S rRNA amplicons) from Arctic frost flowers and underlying sea ice with the long-term goal of informing how biology may influence frost flower chemical and physical processes. Strong agreement between phylochip, T-RFLP, and clone library results, analyzed by MDS, suggests that, in the northwestern Arctic, Hg has bound to different bottom type distributions. Elemental Hg, in contrast, has strong nutrient-like profiles along the west coast of Africa with deep water concentrations as much as 50% of total Hg. Monomethylmercury has pronounced mid-water maxima associated with the oxygen minimum zone, where it is likely to result from either in situ methylation or isopycnal transport from the margin. Vertical profiles suggest that deep-sea sediments are not an important source of monomethylmercury. (Abstract ID 11501)

INTEGRATING GLOBAL PHYTOPLANKTON DATA FROM 1890 TO 2010

Understanding large-scale phytoplankton dynamics requires accurate, multi-decadal measurements of abundance and distribution. Since 1890, marine phytoplankton abundance has been assessed using a diverse range of sensors and observational platforms; inter-calibrating these datasets has been challenging. Consequently, synthesis of historical phytoplankton data have been rare and the need for accurate, long-term assessments of phytoplankton is commonly acknowledged. We derive quantitative indices of phytoplankton abundance from measurements of upper ocean transparency and colour calibrated with direct measurements of surface chlorophyll. The strong correlation and linear scaling of predicted data enabled construction of a comprehensive, globally inter-calibrated phytoplankton time series from 1890 to 2010. The calibrated phytoplankton data reproduced the well-established spatial features of phytoplankton biomass and were strongly correlated with phytoplankton concentration derived from two independent remote sensing platforms discontinuously available since 1978. These results suggest that with careful statistical treatment, it is possible to generate a globally integrated phytoplankton time series extending 120 years into the past. This database may enable new insights in the areas of climate science, biogeochemical cycling, and marine ecosystem structure and functioning on centennial timescales. (Abstract ID 11764)

COMPARISON OF NATURAL AND IMPOUNDED MARSH ACCRETION RATES IN COASTAL DELAWARE

In the face of rising sea level and increasing human pressures, the accretionary status of estuarine marshes is a growing concern among scientists and environmental managers. In coastal Delaware there is a need to determine sediment accumulation and marsh accretion rates for impounded wetlands fringeing Delaware Bay, because these areas particularly vulnerable to flooding and loss during coastal storms. To address this need, we are comparing accretion rates for several impounded marsh systems with baseline rates determined by identical methods for undisturbed marshes in the region. Using Cs-137 and Pb-210 chronologies along with density and loss-on-ignition measurements, we are determining the specific contributions of organic and inorganic sediment accumulation to overall rates of marsh accretion. Results show a high level of spatial variation in rates due to localized factors that moderate mineral sedimentation and vegetation growth. Whereas some of the impounded marsh is accreting at rates below the baseline rates of 3-5 mm/yr, others are accreting within and even above this range. Through ongoing work we are beginning to identify biotic and abiotic conditions that influence the accretionary deficits. (Abstract ID 11318)

BUILDING ON THE SUCCESS OF OCEAN ACIDIFICATION RESEARCH IN THE BROADER CONTEXT OF GLOBAL ENVIRONMENTAL CHANGE

Research into the biological threat of reduced pH, termed Ocean Acidification ( OA), has yielded many insights over the past decade. Moreover, the findings from OA research have been successfully disseminated to a wide audience, extending well beyond the boundaries of the traditional scientific community. There is much to be learnt from the OA community by the fledging research field which is investigating the effects of global environmental change on oceanic biota. In turn, much of the preliminary research into global environmental change reveals that the interplay of multiple environmental stressors on ocean biota results in either significant amplification or diminution of the effects of a sole stressor such as OA. Our growing appreciation of how global environmental change will manifest itself in turn lays down the challenge of understanding the complex interplay of a matrix of changing ocean properties and their biological
implications. We will present examples of how we can better identify and catalogue biological responses, and subsequently predict the sign and magnitude of their feedbacks, by taking a holistic view of the effects of global environmental change. (Abstract ID 9773)

A CLIMATE CHANGE ATLAS FOR THE OCEAN

The increasing likelihood that we will encounter a changing climate in the coming years has major ramifications for both coastal and offshore waters in many biogeographical provinces. Each of these regions is characterized by a range of water bodies with a diverse marine biota. However, their environmental properties will be altered, by varying degrees, in the near future, and there will also be differing impacts on resident marine biota. Within the Exclusive Economic Zone (EEZ) of each nation, particular regions, and some plant and animal species will be more susceptible to change than others. This will raise major issues for policymakers and managers regarding the alteration of the ecosystem services within and the economic value of each national EEZ. Using the format of an Atlas of Ocean Climate Change (Oceanography 24 doi:10.5670/oceanog.2011.42) is the first step in developing a comprehensive assessment what may happen to our seas in the coming decades. We will provide illustrative examples from the New Zealand Atlas that will reveal how such a tool can readily be applied to other oceanic regions. (Abstract ID 9775)

THE EVOLVING ATLANTIC Pb AND Pb ISOTOPE DISTRIBUTION

On numerous cruises during the past 27 years, including the first leg of the US GEOTRACES North Atlantic Transect (US-GT-NAT), we have obtained unimportuned decontaminated deep-sea profile samples for ~1000 Pb concentration analyses and ~500 Pb isotope analyses. Where stations have been reoccupied on decadal time scales (western and eastern North Atlantic), we see Pb decreasing strongly in the upper ventilated ocean (due to the phasing out of Pb gas) and remaining relatively constant in the more slowly ventilated deeper waters. Pb isotope ratios change in the ventilated waters as the proportion of U.S. and European sources varies (the U.S. phased out Pb gas faster than Europe). 208Pb/206Pb, 206Pb/207Pb, and 206Pb/204Pb ratios form near-linear arrays (set up by global U-Th-Pb reservoir evolution) with a scatter exceeding analytical error by a factor of 3-10. Triple isotope plots therefore allow for more subtle determination of Pb sources; e.g. Pb isotope data from the modern Mediterranean outflow is distinctive from the waters that sank from the North Atlantic 80 years ago. MODELING BAROCLINIC TIDES IN THE GULF OF MEXICO

The goal of the study is to document and understand baroclinic tide generation in the Gulf of Mexico. We first validate the barotropic tidal implementation in a Hybrid Coordinate Ocean Model (HYCOM) Gulf of Mexico configuration by comparing simulated tidal amplitudes and phases to available observations. The four main tidal constituents (M2, O1, S2, K1) present in the Gulf of Mexico are well represented when using surface astronomical forcing together with the barotropic tidal transports and elevations prescribed at open boundary locations. The barotropic tides are then investigated by quantifying the location and magnitude of the tidal energy conversion in the Gulf of Mexico as a function of the vertical stratification. We show that the baroclinic components of the tidal velocities are negligible within most of the basin, except in areas with strong topography (e.g. West Florida Shelf, Yucatan Peninsula) where intense internal waves can be generated and can lead to important internal tidal conversion processes. The impact of the model horizontal grid resolution (1/12° and 1/25°) on the representation of the internal wave field is also addressed. (Abstract ID 10520)

SUBMESOSCALE PROCESSES IN THE GULF OF MEXICO

We present a suite of numerical experiments focusing on the impact of submesoscales processes in the Gulf of Mexico throughout the water column. Our focus is on the role of ageostrophic velocities in setting a) the horizontal and vertical mixing of Mississippi river waters, b) the interaction between the river waters and the Loop current and c) the mixing associated with the Loop eddies. Our simulations cover the period 2000-2011 and we consider two nested domains with lateral resolution varying from 1 to 1.6 km covering most of the Gulf. We use Lagrangian tracers, passive tracers and a NPF2 model to quantify transport, both at the surface and at depth. (Abstract ID 10658)

E-CO2 SCHOOL LAB: A SCIENTIFIC VIRTUAL EXPERIENCE FOR STUDENTS.

Experimental approach is widely recognized to be the most effective method in science teaching, but lack of time and funds sometimes prevent its application. E-CO2 School Lab is a virtual interactive laboratory for students from K7 to K12 dealing with Ocean Acidification Problem. E-CO2 School Lab offers three perturbation experiments based on reaction of calcareous red alga (Corallinaceae – Rhodophyta) in a high CO2-world. Students handle two virtual aquariums, the first representing actual condition, the second IPCC forecasted conditions for year 2100, taking several measurement of the algal growth and development. The Lab is supported by a large and multi medial miniWiki, where students can reach easily all information that they may need. E-CO2 School Lab is a team-work: even though it can be played individually like a video-game, the real aim is to stimulate discussion about Ocean Acidification and its impact on marine ecosystem. The teacher, whose leading role remains fundamental, can tailor the experience on his/her class level and on demand (teacher’s guide disposable on line). E-CO2 School Lab, available free on line, is proposed to meet the need of experimental teaching of science, with low time and fund investments. (Abstract ID 9615)

COMPARING THE TROPHIC ECOLOGY OF MESOPHTIC AND EUPHTHIC FISHES USING COMPOUND SPECIFIC ISOTOPE ANALYSIS OF AMINO ACIDS

The trophic ecologies of eleven fish genera in six families from mesophotic (50-120m) and euphotic (~40m) reef ecosystems were assessed using bulk tissue and individual amino acid stable isotope compositions. Reef fishes were collected using subsamplers and closed circuit rebreathers from the waters near the Hawaiian Islands of Maui and Lanai. Using the difference between nitrogen isotope values of glutamic acid and phenylalanine we calculated the trophic position of multiple reef fishes to address ontogenetic and depth related differences. Slight differences in trophic position are seen between the two depth ranges, however opposing trends between fishes with planktonic and benthic driven feeding strategies were found. Bulk tissue carbon isotopic composition revealed distinction between these two feeding styles across depth groupings. The remaining trophic and source amino acids were compared among groupings to investigate the potential drivers of the trends. Depth related disparities in trophic ecology have the potential to impact the use of ecosystem based management models in Hawaiian reefs as well as the refugial potential of mesophotic reef ecosystems. (Abstract ID 12469)

BACTERIAL COMMUNITY STRUCTURE OF A FRESHWATER SPRING IMPACTED BY HYDRILLA

Hydrilla verticillata is one of the most invasive aquatic plant species and causes ecological and economical problems in freshwater systems. We will test the hypothesis that Hydrilla alters the normal bacterial community by investigating bacterial populations of Wakulla Spring which is impacted by Hydrilla. Water samples were collected from Wakulla Spring and two conduits (not impacted by Hydrilla) over an annual period. Two liters of the samples from each site were filtered through 0.2µm filters and stored at -20°C for further processing. Culturable bacteria were enumerated by the spread plate method using R2A medium and colony forming units (CFU) enumerated after one week. Bacterial DNA was extracted from 0.2µm filters, amplified with universal rRNA gene primers. Amplified products were separated by DGGE and prominent bands excised, reamplified and sequenced. Results revealed some differences between the two springs in both total CFU and the DGGE profiles. The next step will be cloning of environmental DNA from Wakulla Spring. (Abstract ID 9779)

SPATIAL AND TEMPORAL BIO-OPTICAL VARIABILITY AT LUCINDA JETTY COASTAL OBSERVATORY: IMPLICATIONS FOR CALIBRATION AND VALIDATION OF OCEAN COLOUR SENSORS

The Lucinda Jetty Coastal Observatory (LJCO) was established as part of Australia's Integrated Marine Observing System (IMOS) to provide continuous above and below water optical measurements in complex coastal waters. This data stream is a critical input towards improving and validating coastal and continental shelf satellite ocean colour products. Field programs were carried out in April and November 2010 to characterize the spatial and temporal scales of bio-optical variability at and around LJCO, and to determine whether the parameters measured continuously at the site were representative of the surrounding local waters. Continuous instrumental data, as well as in situ water samples to be analysed by laboratory methods, were collected regularly at LJCO and from sites close to LJCO over a 4-day period. Preliminary results show low scales of spatial and temporal variations in the measured bio-optical parameters indicating that the continuous instrumental data collected at LJCO is representative of a larger footprint around the site. Implications of these findings for matchup analysis of above and below water optical parameters for current ocean colour missions will be discussed. (Abstract ID 12790)

VENTILATION OF THE TROPICAL ATLANTIC BY EQUATORIAL DEEP JETS

Vertically alternating deep zonal jets of short vertical wavelength were discovered in the equatorial oceans more than 30 years ago. In the Atlantic, these jets have periods of about 4.5 years and are observed to be coherent across the equatorial basin. They are known to transport deep water mass characteristics from the western boundary towards the eastern equatorial basin. Here we present long-term velocity and water mass observations at intermediate depths showing that the equatorial deep jet causes a pulsating oxygen flux from the well-ventilated western boundary region towards the weakly ventilated eastern Atlantic. The oxygen supply to the equatorial Atlantic east of 23°W due to deep jets is estimated to be up to 2.5 mmol kg⁻¹ yr⁻¹. It contributes to the broad equatorial oxygen maximum with latitude seen at intermediate depths that is typically not present in state of the art global climate-biogeochemistry models. Poleward eddy fluxes away from the equator are in turn crucial for the ventilation of the tropical oxygen minimum zones. Simple parameterizations of deep jets for coarse-resolution models in terms of regional varying eddy diffusivities are suggested. (Abstract ID 10363)

OCEAN TRACKING NETWORK ACTIVITIES IN CANADIAN'S BAY OF FUNDY

The Ocean Tracking Network's approach to the integration of biological and environmental data is expected to lead to an international standard for the inclusion of animal behavior data into the Global Ocean Observing System. Canada's Bay of Fundy, with the highest tides in the world and fiercely turbulent environment has been chosen as a location to investigate effectiveness of acoustic telemetry technology over a range of research issues including species at risk, climate change and tidal power. Here we describe regional scale data processing and associated database management systems currently being used to support a rapidly expanding complex of independently operated acoustic telemetry based sensor tag deployment and tracking projects. In addition to an overview of results to date, we give details of OTN's integrated approach to the collection, processing and quality control of information about how, when and where the various instruments are deployed in the field as well as give descriptions of: PostgreSQL/POSTGIS data base, Web Mapping and Feature Services, Rstudio data visualizations and discovery metadata records. (Abstract ID 11084)

TOWARD AN IMPROVED DESCRIPTION OF UNCERTAINTIES IN OCEAN SIMULATIONS: EFFECT OF LOCAL ANAMORPHIC TRANSFORMATIONS ON SPATIAL CORRELATIONS

In this presentation, we investigate how the description of uncertainties in ocean simulations can be improved by applying local anamorphic transformations to the model variables, assuming the joint Gaussianity for the transformed variables rather than for the original variables. It is first shown that local transformations can be derived from a simple histogram description of the marginal distributions. Two advantages of this solution for large size applications are the conciseness and the numerical efficiency of the description. Several oceanographic examples are examined to evaluate the effect of the using piecewise linear local anamorphic transformations on the spatial correlation structures. These examples include (i) stochastic ensemble descriptions of the effect of atmospheric uncertainties on the ocean mixed layer and their consequences on ecosystem models, and (ii) non-stochastic ensemble descriptions of uncertainties in sea-ice properties and ecosystem predictions. The results indicate that the transformations tend to increase the correlation radius essentially when the variables exhibit nonlinear behaviour, and thereby improve the benefit that can be expected from a given observation network integrated in an assimilative system. CONTAMINANTS IN ANTARCTIC FUR SEALS: ASSESSMENT OF DIET AND THE DECLINE IN CONTAMINANT BODY BURDEN OF FEMALES FROM PLACENTAL AND LACTATION TRANSFER

Persistent organic pollutants (POPs) and mercury, contaminants that bioaccumulate in upper trophic level organisms, were detected in a top Antarctic Peninsula predator, Antarctic fur seals. Female seals can decrease their body burden of contaminants via placental and lactation transfer of contaminant residues from morn to pup. Previously breeding females were found to have significantly lower concentrations of certain POPs (p,p’ DDE, chlordane, HCHs and less metabolizable PCBs) in their milk than first breeding females, likely due to transfer of their POP burden from mother to pup in earlier years. POPs in milk samples from Antarctic fur seals collected over the last decade were evaluated to further assess this trend. POPs, mercury, carbon and nitrogen stable isotopes can also provide insights into long-term and short-term dietary preferences of marine predators. Chemical tracers unique to fur seal prey (e.g., fish and krill) were identified, and the contributions of these prey items to Antarctic fur seal diets over the last decade were assessed. By evaluating the dietary preferences of these seals the transfer of contaminants across trophic levels is better understood. (Abstract ID 11732)
RESOLVING FALLOUT VERSUS RUNOFF SOURCES OF FUKUSHIMA RADIOACTIVITY USING RADIAISON ISOTOPES

Radion isotopes derive from sediments within groundwater aquifers or coastal margins, thus they are useful in tracing the pathway of water masses originating from the coast. Here, we present the results of radium and cesium isotope and ocean drifter data collected along the Japanese coast and within the Kuroshio Current in June of 2011. The objective of this research is to identify the pathway and flux of radioactive material from the Fukushima Dai-ichi reactors to the ocean. Early data indicate that short-lived Ra-223 and Ra-224 were elevated at several locations where Fukishima-derived cesium concentrations were highest. This implies a coastal source for Cs from direct discharges to the ocean, rather than an atmospheric fallout pathway at these locations and times. We use drifter data in conjunction with short and long-lived (Ra-226 and Ra-228) radium isotopes to estimate the approximate age, source and transit time of the water masses that contained the highest cesium levels. To our knowledge, this is the first study to use naturally occurring radium isotopes to study the pathway and source of nuclear materials in the environment. (Abstract ID 11978)

DISTRIBUTION OF CHEMICAL ENERGY IN A RISING HYDROTHERMAL PLUME OF THE LAU BASIN

Recent studies suggest that both biotic and abiotic processes modify hydrothermal chemical fluxes subsequent to venting. The availability of chemical energy for chemosynthesis and carbon fixation is a fundamental coupling between these processes. As part of our investigation of the rising plume chemistry of Lau Basin vents we examine this coupling by comparing geochemical observations with modeled mineral formation and the potential availability of chemical energy. The availability of chemical energy for a range of chemosynthetic metabolisms is estimated for the rising plume of ABE1 vent using a coupled physical transport and equilibrium reaction path model. Physical transport is modeled using a turbulence resolving computational fluid dynamics simulation. Speciation of vent derived electron donors and seawater derived electron acceptors is modeled using equilibrium reaction path modeling. The Gibbs free energy available for chemosynthesis is calculated on the basis of the resulting chemical distributions. We are currently validating this initial simulation using a range of sample measurements. Our goal is to build upon this framework and ultimately develop a coupled biogeochemical and ecological model of hydrothermal plumes. (Abstract ID 11943)

FEEDING ECOLGY OF BAY ANCHOVY (ANCHOA MITCHILLI) IN THE MARYLAND COASTAL BAYS

Bay anchovy, anchaoa mitchilli is a small silvery forage fish. It is an important marine species because of its significant biomass in marine and estuarine food webs, playing an important ecological link between plankton production and higher piscivorous trophic levels. The feeding ecology of the bay anchovy was studied based on data collected in June 2011 from 6 sites in the MCBs. Gut content analysis was carried out on 88 bay anchovies. Diet composition consisted of copepods, crab larvae, mysids, shrimp larvae, amphipods, cumaceans, ostracods, fish larvae, isopods and eggs. Copepods were the most abundant (93%) and frequent (70%) prey item while cumaceans, ostracods, isopods, and fish larvae were least (5% C<3% and 50%<10%). Throughout the different areas sampled there was a distinct change in the amounts and variety of the food sources found. (Abstract ID 9667)

AMS OCEAN WEATHER, AND CLIMATE STUDIES RAISING EARTH SCIENCE LITERACY ONE STUDENT AT A TIME

Increasing students earth science literacy is a primary goal of the American Meteorological Society (AMS). Supported by NOAA, NASA, and NSF, AMS Ocean Studies is one of three introductory undergraduate courses developed and offered by the AMS that engages students in the geosciences by utilizing real-world, environmental data. AMS Ocean Studies is an all-inclusive course package, containing both printed and online materials. The 2011 Japan
tsunami, the 2010 Gulf oil spill, along with a detailed look at the essential role the ocean plays in Earth's climate system are only a few of the topics covered in the newly revised Ocean Studies textbook. Through a course website, students also dive into online resources from NOAA and other leading scientific organizations. To better understand complex oceanographic principles, such as the Coriolis force and plate tectonics, an interactive globe is also included. AMS Ocean Studies has been adopted by almost six dozen institutions throughout the country with the U.S. Navy being one of the largest adopters. Through AMS Ocean, Weather, and Climate Studies, AMS aims to interest all students in the geosciences. (Abstract ID 9451)

EVALUATION OF THE MESO SCALE ACTIVITY IN THE MERCATOR-OCEAN GLOBAL EDDY-RESOLVING MODEL (1/12).

In 2007, Mercator Ocean has initiated for operational oceanography application the development of a global ocean/sea ice high-resolution model (1/12), based on the NEMO OGCM. Since this first configuration, updated physical parameterizations have been implemented and evaluated in various inter annual experiments. The last experiment has been driven over the last decade (2000-2009) by the EC-Antarctic reanalysis fluxes. In order to better capture high frequency variability, the atmospheric forcing is sampled to the 3H and applied using Okubo Weiss parameter has been developed and applied on the model outputs. The results, in term of eddies number, eddies lifetime and eddies trajectories, are compared with the altimetric data ones. (Abstract ID 11229)

DIVERSITY AND ENVIRONMENTAL DISTRIBUTION OF LONG CHAIN POLYAMINES ROLE IN GLOBAL BIOGEOCHEMICAL CYCLES AND PALEOECEANOGRAPHIC RECONSTRUCTION.

Long-chain polyamines (LCPAs) produced by diatoms for biomineralization of their cell walls play a central biogeochemical role, linking the cycling of organic matter with the cycling of silicon. At depth, their distribution, molecular diversity and fate in the upper ocean and in sediments remain to be fully characterized. We used HPLC/ESI-MS: high resolution mass spectrometry (TOF-MS) as well as 1H, 13C NMR spectroscopy to characterize LCPAs at the molecular level in mixed marine plankton communities and in the sedimentary record of the Pacific Ocean, Bering Sea, Southern Ocean and Puget Sound estuary. An astonishing variety of over 100 natural LCPAs with complex distribution patterns was found in each sample and clear regional differences were shown in composition and structural characteristics, likely reflecting differences in diatom flora. We will show that LCPAs constitute a valuable substrate for compound-specific radiocarbon (Δ14C) dating, in regions where production and/or preservation of carbon is poor, such as in the Southern Ocean and the Equatorial and Northeastern Pacific Ocean. This new class of biomarker offers a promising tool to advance our understanding of the feedbacks between diatom physiology, biogeochemical cycles and climate. (Abstract ID 10685)

A PARTICLE FILTER FOR HIGH DIMENSIONAL SYSTEMS WITH APPLICATION TO OCEAN BIOGEOCHEMISTRY.

Particle filters are sequential data assimilation algorithms that produce estimates for the ocean state and its uncertainty. An outstanding problem is the successful application to high dimensional systems, such as characterizes most realistic oceanographic models. The fact that small ensembles must represent large state spaces leads to degeneracy and failure in particle filter applications due to weight collapse. Few workable solutions exist, with the exception of the approximate ensemble Kalman filter. We have developed a new approach applicable to large dimension systems. The idea is that at every single step, a particle filter is not only applied in the time domain, but also applied in the spatial domain. That is, a sweep is made through the spatial grid at each time step (and is smoothed) thereby providing for representative samples from target distribution that characterizes the ocean state. This appears to mitigate weight collapse in large dimension systems. An application for a 1-D ocean biogeochemical model using the Bermuda Atlantic Time Series is used to illustrate and test the approach. (Abstract ID 10738)

ESTIMATING PHYTOPLANKTON SIZE FROM HIGH-FREQUENCY FLUCTUATIONS IN SIMPLE OPTICAL MEASUREMENTS.

Particle size is a critical attribute of phytoplankton communities that is difficult to measure in situ at broad spatial and temporal scales. Theoretical and experimental work by K. Shifrin has shown that high-frequency fluctuations in optical beam attenuation contain information about particle size. Here we apply a similar principle to estimate mean particle size from optical backscattering and chlorophyll fluorescence timeseries. Fluctuations in backscattering during a laboratory aggregation experiment were used to estimate mean particle size from optical backscattering and chlorophyll fluorescence measured in situ during the North Atlantic Bloom 2008 project were used to determine the dominant phytoplankton size class. Both laboratory and field results compare well with independent measurements. Our results suggest that chlorophyll fluorometers and scatterometers already deployed on ships, moorings, and autonomous platforms can be used to identify both the dominant phytoplankton size class and the dominant overall particle size class (< 1 cm) at broad spatial and temporal scales. (Abstract ID 11410)

CROSS-SHELFE TRANSPORTS: THE PROBLEM THAT DOES NOT DIE

Cross-shelf transports undoubtedly occur in the coastal ocean: inner shelf waters are almost always salty. These exchanges are critical for nutrient cycling, sediment transport and contaminant dispersal, to name just a few. From a physical perspective, the problem is hard because Earth’s rotation inhibits steady flow across isobaths, so that cross-shelf exchanges must be dissipative, episodic, or unusually intense. Some types of cross-shelf transports that are roughly understood, including wind-driven upwelling, surf zone undertow, and shear dispersion. Attention here is on the difficulties and opportunities associated with a few illustrative, less-understood mechanisms. For exchanges across a shelfbreak front, time-dependence and nonlinearity allow net fluxes, but the observational problem is difficult because the exchange is inefficient. In bottom boundary layers, turbulent frictional effects allow cross-shelf transports, but we still do not understand the bounds of buoyancy arrest. Buoyancy currents, unless they are very large, tend to die out alongshore, implying cross-shelf dispersal, but the mechanism and rates are, to date, poorly understood. Progress will likely involve using models that are evaluated against the more observable integrated aspects of measurements. (Abstract ID 9718)

Brink, K. H., Woods Hole Oceanographic Institution, Woods Hole, MA, USA, kbrink@WHOI.EDU

BUOYANCY ARREST AND STEADY CROSS-SHELFE FLOW

Buoyancy arrest results from near-bottom cross-isobath Ekman flow transporting lighter or denser water across isobaths. The resulting density gradients, through a thermal wind balance, lead to vanishing bottom velocity and bottom stress. In an idealized case, the remaining steady flow is geostrophically balanced, and so cross-isobath flow is prohibited. Scalars and a sequence of idealized, fully nonlinear, numerical model runs are used to explore the evolution of an imposed cross-isobath flow at the shelf edge. Far from the inflow, buoyancy arrest occurs and the steady current’s width follows a scaling similar to that of Chapman and Lentz (1977). Closer to the prescribed forcing, there is a steady transition region where arrest is incomplete and cross-isobath flow is allowed. The alongshore scale for adjustment to arrest increases with the imposed volume flux, and decreases as the measurement of stratification or bottom slope increases. For many reasonable continental shelf settings, this adjustment scale is so large that steady, completely arrested conditions should not be expected. (Abstract ID 9752)
Nitrogen Isotopes and Community DNA and RNA Datasets Support a Role for Nitrite Oxidation Throughout the Oxygen Minimum Zone off Northern Chile

Despite the importance of the oxygen minimum zone (OMZ) in the Arabian Sea and eastern tropical Pacific, OMZ microbial N-cycling pathways, their environmental constraints and overall biogeochemical impact remain unresolved. To explore these issues, we present N-15 and O-18 nitrate and N-15 nitrite isotope distributions along with metagenomic and metatranscriptomic analyses of key nitrogen metabolism genes in the OMZ off northern Chile. Depth profiles showed a delta N-15 offset between co-occurring nitrate and nitrite of 30 to 40% throughout the OMZ. This offset is greater than expected from dissimilatory nitrate reduction and consistent with additional processes such as nitrite oxidation enhancing this separation. Deviations in the expected N-15 and O-18 nitrate relationship also suggest an important role for this process. Indeed, community DNA and RNA datasets contained high numbers of sequences encoding enzymes of nitrite oxidation, including nitrite oxidoreductase (NirB) and the nitrate reductase (NarG) of an anammox bacterium, which likely functions in the oxidative direction during anammox. Together, these data implicate nitrite oxidation, potentially via nitrification or anammox, as a significant contribution to nitrogen cycling in the OMZ. (Abstract ID 10424)
observed and recorded using 100Hz accelerometer sampling and high-speed video among 7 different great scallops. We demonstrate that multiple parameters in the time and probability domain can statistically differentiate among events. Dr for feeding and escape events decreased by 50% when sampling at <0.1Hz. Our analyses demonstrate additional problems associated with aliasing and how activity and energy-budget estimates can be compromised and misinterpreted. We recommend that high-frequency accelerometer sampling be used in similar (field) studies. If battery-storage is limited, we also recommend archiving the events via an onboard algorithm that determines the highest likelihood and subsequent archiving of the various event-classes of interest. (Abstract ID 10591)

NITROGEN FIXATION - A NEW SOURCE OF NITROGEN IN THE CHANGING WESTERN ARCTIC?

Pelagic nitrogen fixation is generally confined to relatively calm, oligotrophic waters with temperatures greater than 20C. It follows then that it would be unlikely in the Arctic. Despite this reasoning, nitrogen fixation was measured in surface waters at seven out of seven sites sampled in the coastal Chukchi Sea in August 2011. To measure fixation rates we incubated surface water with N15-labeled nitrogen gas for 24 hours under in situ conditions (24 hour light at 5C). Rates in the >0.7um fraction ranged from 0.01 to 0.52 nmol N/L hr with 23 to 92% occurring in the >3um fraction. To our knowledge these are the first measurements of nitrogen fixation in the Arctic and they raise a number of questions. Have others tried to measure it in the past but did not see detectable rates? Can we measure it now because the predicted increased nitrogen demand (longer ice free growing season) and increased nitrogen loss (enhanced denitrification) is coming to pass? In the future will nitrogen fixation be an increasingly viable way to make a living for Arctic microbes? (Abstract ID 12131)

SPATIOTEMPORAL TRENDS OF MATING AGGREGATIONS IN NURSE SHARKS (GINGLYMOSOMATA CIRRATUM) AROUND CAPE ELEUTHERA, THE BAHAMAS

The reproductive ecology and behaviour of most large sharks remains an enigma, largely due to the logistical challenges of observing specific behaviours in these highly mobile and wide ranging species. Understanding and promoting reproductive success is critical to the effective conservation and management, yet at present this is a minimally investigated area. The nurse shark (Ginglymostoma cirratum) is a highly abundant species found throughout the tropical and sub-tropical Atlantic which is known to form dense mating aggregations in shallow coastal habitats, making them easily accessible for observation. Since May 2010 this study has documented timing and location of mating aggregations of nurse sharks at 6 shallow coastal areas, characterized by sand, rubble and often mangrove presence, around Cape Eleuthera, The Bahamas. The greatest number of individuals observed was 19 with the majority of mating behaviour occurring in the month of June. Abiotic factors monitored included tidal state, water temperature and sediment type. Future research will assess the degree of site fidelity exhibited by individuals to specific aggregation sites and investigate the potential effects of essential habitat loss. (Abstract ID 12837)

LEADERSHIP EFFECTING CHANGE: RESEARCH, OUTREACH AND EDUCATION IN THE BAHAMAS

The Island School serves as a catalyst in the global transition to a more livable future through three institutional keystones: Developing an intimate sense of place in students through immersion experiences in the natural and cultural environment; Modeling sustainability of individual lifestyles, larger communities, and the systems that support them; Creating an intentional community whose members are cognizant of their abilities, limitations, and effect on others. The mantra of the school is leadership effecting change and a key avenue is conducting research alongside experts at the Cape Eleuthera Institute (CEI). The mission of CEI is to promote the conservation of the tropical marine and coastal ecosystems of Eleuthera, The Bahamas, and the greater Caribbean by facilitating the research of resident and visiting scientists, supporting the education of students at all levels, and promoting outreach efforts to enhance the conservation awareness of local and global communities. CEI leads international conservation efforts to ensure the long-term health of local and global natural resources through sustainable approaches to their use, enjoyment, and protection. THE DIVERSITY, DISTRIBUTION AND DEMOGRAPHIC POPULATION STRUCTURE OF WESTERN WATER ESPLANALBOMARINUS IN THE NORTHEAST EXUMA SOUND, THE BAHAMAS.

The Exuma Sound is a deep water inlet of the Atlantic Ocean ranging in depth from 500 – 2000 m and characterized by steep walls along its margin. The sound is in close proximity to land, facilitating the sustained ecological investigation of its deep water esplanalbomarinus fauna. To date, 58 deep water longline surveys have been conducted (depth: 472.6 – 1024.1 m; seabed temperature: 15.6 – 59.9 C), resulting in the capture of 133 sharks from nine different species. Preliminary analysis suggests that water depth and bottom temperature are significant predictors for the presence or absence of Squallus cubensis, Mustelus canis insularis, Centrophorus granulosus, Hexanchus nakamura and Centroscymnus owstoni. There were no predictable trends in the abundance of Hexanchus griseus, Centrophorus raiuadag, Galeus ptilorhynchus or Pseudotriakis microdon. Species richness declined significantly with increasing distances from the edge of the Exuma Sound and increased significantly with higher seabed water temperatures. Significantly skewed sex ratios exist for a number of species. Surveys are ongoing and all results are preliminary. (Abstract ID 12851)

RAPID INCREASE IN ACCUMULATION RATE AND SHIFT IN SEDIMENTARY REGIME IN THE NE GULF OF MEXICO FOLLOWING THE 2010 BP BLOWOUT EVENT

Multicores from >40 sites along the NE Gulf of Mexico continental slope recovered a 1-6 cm thick well-defined, internally stratified medium-dark brown surface layer of sandy mud. Separated by a sharp basal contact, this surface layer is finer grained and has a higher organic content than underlying sediments. It also exhibits a hydrocarbon signal similar to that of the subsurface oil plume detected following the BP blowout event, whereas underlying sediments show a distinctly different, land-derived hydrocarbon signal. Short-lived radionuclides (137Cs, 210Pb, 7Be, 134/137Cs) geochronology indicates that the entire 1- 6 cm-thick surface layer was deposited in less than six months following the blowout event, at mass accumulation rates ranging from 0.6 to 20 g/cm2/yr, compared to 0.02 to 0.2 g/cm2/yr for underlying sediments. Thus, a distinct change in sediment texture and composition accompanied by a 1-2 order-of-magnitude increase in accumulation rate over 6 months can be directly related geochemically to the 2010 BP blowout event. (Abstract ID 11788)

MODELING THE AMAZON RIVER PLUME

The Amazon River Plume spreads fresh and optically dark water across thousands of square kilometers of the western tropical North Atlantic. The plume creates a salinity driven barrier to vertical mixing, and often heats as much as 2 degrees C above surrounding waters. We present a 1/6 degree HYCOM implementation for the tropical Atlantic Ocean that is focused on resolving surface plume processes and their associated biogeochemical cycling. The distribution and variability of the model salinity is consistent with field observations. The model shows seasonal variations in the transport of freshwater, with northward flow in winter and spring, and eastward flow in summer and fall. The north equatorial countercurrent serves as a carrier for this eastward transport of freshwater, which rides on its northern flank, and is sheared off in waves at the junction of the countercurrent and the westward flowing subtropical gyre return flow. Little of the Amazon River water moves into the equatorial region, most is passed northward to in to the subtropics. Simulations exploring the role of the river in
modulating the physics, air-sea exchange and biogeochemical cycling in the tropics highlight the importance of the river in this region. (Abstract ID 11957)

IMPACT OF OCEAN CONDITIONS ON ENDANGERED SALMON RESIDENCE IN A RIVER PLUME: PRELIMINARY RESULTS AND MANAGEMENT IMPLICATIONS FROM A MARINE TELEMETRY ARRAY

Three years of tracking acoustically tagged juvenile Spring Chinook salmon during their early marine migration, a critical survival period, has shown that survival in the Columbia River plume region can vary substantially; mean overall survival 2008-2010 was 53% with SD 17%. Residence time in the plume region appears to explain some of this variability, and our preliminary results suggest that residence time covaries with coastal upwelling and local sea-surface temperature. Daily survival rates appear to improve in the coastal ocean beyond the plume region, so it is conceivable that manipulating river spill to align ocean entry with conditions favorable to a shorter plume residency could improve overall marine survival. (Abstract ID 12395)

Porites spp. and algal turf. Coral-macroalgal interactions influence oxygen conditions above the zone of interaction, we suggest future studies explore the play a diminutive role in oxygen dynamics. As the metabolic byproducts of algal turf appear to (50µg/ml ampicillin) was added to thicker above algal turf and the zone of interaction (<500 – 2500µm). Oxygen extremes in the boundary layer (DBL) in light and dark above the surfaces of interaction was measured. As water flow increased, DBL height decreased, but remained for developing the model system to include surface wave as a primer for air-sea exchange of momentum and (turbulent) energy from atmosphere to the ocean. (Abstract ID 11767)

Brown, A. L., California State University, Northridge, USA, brown.anya@gmail.com

FLOW-REGULATED, ALGAL TURF CONTROL OF OXYGEN DYNAMICS WITHIN INTERACTIONS OF MASSIVE PORITES SPP. AND ALGAL TURF

Extreme oxygen concentrations can lead to coral tissue necrosis. We examined how water flow and the members of coral-macroalgal interactions influence oxygen concentrations above the zone of interaction between massive Porites spp. and algal turf. Coral-macroalgal interactions were exposed to three flow speeds (0.7, 14 cm s⁻¹), and the height of the diffusive boundary layer (DBL) in light and dark above the surfaces of Porites, algal turf and their zone of interaction was measured. As water flow increased, DBL height decreased, but remained thicker above algal turf and the zone of interaction (~<00 – 2500µm). Oxygen extremes in light and dark above the zone of interaction were most similar to concentrations above algal turf. To assess the influence of microbes on oxygen concentrations above each surface, antibiotic (50g/ml ampicillin) was added to Porites-algal turf interactions; the results suggest microbes play a diminutive role in oxygen dynamics. As the metabolic byproducts of algal turf appear to influence oxygen concentrations above the zone of interaction, we suggest future studies explore the role of oxygen extremes on the outcome of coral-algal interactions. RIP CURRENT VERTICAL STRUCTURE

Field observations of mean Eulerian rip current velocities are compared with numerical Delft3D model simulations to examine the mechanisms shaping the vertical structure of the flow under varying hydrodynamic conditions. Waves, bathymetry, tidal elevation and currents were measured at a beach in Monterey Bay, CA, comprised of quasi-periodic rip channels. Vertical rip current profiles were obtained using bottom mounted current profilers. In the rip channel, inside of the surf zone, the current was depth uniform, while farther offshore, outside of the surf zone, the current was surface dominated. In Delft3D, the hydrodynamic flow conditions were coupled to the short-wave propagation, and the effects of wave stresses, turbulent eddy viscosity, and Coriolis force were included. The effect of wave groups on the rip current vertical structure is evaluated by comparing simulations with regular unidirectional waves versus wave groups constructed from measured directional wave spectra. The response of the modeled velocity profiles to the (vertical) variation of turbulent eddy viscosity, Coriolis force, vortex force and wave forcing are evaluated to establish the dominant processes determining the vertical structure of rip current flows. N AND P ACCUMULATION IN THALASSIOSIRA PSEUDONANA UNDER DIFFERENT N: P SUPPLY RATIOS AT SATURATING CONCENTRATIONS: IMPLICATIONS FOR FOOD WEBS

It is well established that the biomass N:P ratio of phytoplankton is highly dependent on the N:P availability ratio when one of the nutrients is supplied under growth-limiting conditions. Few data exist on the variability of cellular N:P when nutrients are supplied in excess, but at different ratios. We studied the effect of different N:P ratios (ranging from much less to much greater than, Redfield proportions) at saturating nutrient concentrations on the N:P ratio of the diatoms Thalassiosira pseudonana maintained in turbidostats at two light intensities. The cellular N:P ratio varied positively with supply ratio, but to a lesser proportional extent than the supply ratio. Cells growing under high light exhibited a greater N:P ratio range than cells grown under low light. These results suggest that phytoplankton in euphotic conditions continue to physiologically adjust their N:P ratios even when nutrients are at saturating levels. Thus, in the context of ecological stoichiometric theory, waters that are considered nutrient saturated for growth may still impose a ‘nutrient effect’ via the particulate N and P that becomes available to higher trophic levels. BIOGEOCHEMICAL SENSING SYSTEMS FOR AUTONOMOUS PROFILING FLOATS

A bio-optical sensor system for profiling floats to be used for ocean color satellite calibration and validation and ocean carbon studies was developed. The challenge of realizing the biogeochemical float is in augmenting the proven Argo float with an expanded sensor system that is robust, efficient, and economical so as to achieve satisfactory mission duration. Sathalian and WET Labs jointly developed the sensor system and collaborated with Teledyne Webb Research to integrate it with the APEX float. The sensor system includes an integrating hub that manages up to six additional instruments. The hub controls power switching, implements sampling strategies, and logs data minimizing energy consumption and data size thus maximizing float mission duration. The modular sensor system design allows for building user specified variants. The initial system provided upwelling and downwelling radiometry at four wavelengths, scattering at three wavelengths, beam attenuation, chlorophyll, and CDOM measurements to complement core float sensors for pressure, temperature, salinity and dissolved oxygen. The system architecture and performance are described with emphasis on data quality and the impact on float energy budget and thus mission duration. Initial deployment results are presented. ON THE CHANGING SEQUESTRATION OF NATURAL AND ANTHROPOGENIC CARBON AND EXPORT FROM THE WEDDELL GYRE AT DEPTH

In the Southern Ocean, the Weddell Gyre is regarded as the primary location for the formation of deep and bottom waters and sequestration of carbon, nutrients and atmospheric gases. Major quantities of dense, cold waters generated near and on the Antarctic continental shelf spill down the slopes entraining surrounding water masses as they descend. Circulating northwards the waters are subsequently exported into the mid-latitude Southern Ocean, spreading globally at depth, an integral component of the southern closure of the meridional overturning circulation. Measurements of CFCs, SF6 and the inorganic carbon system from two cruises - extending from the Antarctic Peninsula, along the South Scotia Ridge and the edge of the Weddell Basin to 30°E - conducted as part of the UK ANDREX (Antarctic Deep Water Rates of Export) project in 2009-2010 are used to investigate this process, in particular the accumulation, storage and transport of natural and anthropogenic carbon in Antarctic Bottom Water and its export from the gyre. Historical comparisons with GLODAP-based estimates enable the assessment of changing carbon inventories, fluxes and water mass formation rates within the region. (Abstract ID 12518)

AN OBSERVATIONAL/MODELING INVESTIGATION OF THE MID-ATLANTIC COLD POOL: EVOLUTION AND VARIABILITY

The Mid-Atlantic (MA) Cold Pool (CP) is a distinctive along-shelf band of remnant winter water that is bottom-trapped over the continental shelf between Georges Bank (GB) and Cape Hatteras between May and November each year. CP presence strongly influences the MA ecosystem including fisheries. During the summer, CP water flows southwestward from GB, gradually warming and eroding due to a poorly understood blend of vertical and horizontal mixing processes; before finally losing its identity in early fall during a rapid turnover. Beginning in 2007, the fleet of Slocum gliders of the Mid Atlantic Regional Association Coastal Ocean Observing System (MARACOOS) have been used in an ongoing series of cross-shelf and lateral zig-zag alongshelf water property transect measurements - enabling us to map CP configurations at different phases of CP seasonal evolution. The simultaneous glider optical measurements are being used to map some of the relevant oceanic biological fields. The assimilation of these glider data into a pair of MARACOOS numerical models is enabling more extensive mapping, volume estimation, and future CP dynamics elucidation and forecasting. CHARACTERIZING THE SEA ICE ALGAL COMMUNITY OF THE BELLINGSHAUSEN/AMUNDSEN SEAS

While dense blooms of sea ice algae are known to form in the Ross and Weddell Seas, the ice-algal community of the Bellinghausen/Amundsen Seas has received little attention. However, recent modeling work suggests this region may be among the most favorable ice-algal habitat in the world, due to persistent summer sea ice cover. We examined the ice-algal community of the Bellinghausen/Amundsen Seas, sampling 16 stations in a variety of ice types at the height of the austral summer (December 2010-January 2011) for chlorophyll a (Chl a), accessory pigments, particulate carbon and nitrogen, and cell counts. Preliminary results indicate marked spatial variability, with concentrated ice-algal biomass at some stations (Chl a >240 µg L-1), and very little at others (Chl a <2 µg L-1). Half of all stations exhibited pronounced Chl a maxima in the bottom 10 cm of ice, but biomass maxima were also observed in the interior and at the top of ice cores. We will interpret these highly variable biomass distributions in the context of sea ice chemical (nutrients) and physical (snow cover, thickness, brine volume) characteristics. (Abstract ID 12525)

SEA LEVEL ANOMALIES WITH A TIME SCALE OF WEEKS IN CHESAPEAKE BAY AND ALONG THE MID-ATLANTIC COAST

Non-tidal coastal sea level variability reflects the combined influence of a variety of processes, including storms and long-term global climate change. The focus of this study is on time scales between the synoptic scale of passing weather systems, including storms and fronts (days), and seasonal variations (months). In recent years, significant sea level anomalies with a time scale of weeks have been observed along the U.S. east coast. For example, in summer 2009, non-storm elevated water levels over a period of several weeks led to minor coastal flooding and prompted a NOAA investigation. During May 2011, an unusual high-water anomaly in mid-Atlantic coastal areas interfered with aerial mapping surveys of submerged aquatic vegetation (SAV) and led to concern about stress to SAV due to decreased light availability. In addition to individual event case studies, results from an analysis of a multi-station data set, using locations in the Chesapeake Bay and mid-Atlantic coast, will be reported. This broader analysis investigated defining characteristics, spatial coherence, and temporal trends of the sea level anomalies with a time scale of weeks. (Abstract ID 12274)
STOKES DRIFT DUE TO OCEAN SURFACE WAVES UNDER TROPICAL CYCLONE (HURRICANE) CONDITIONS

Significant efforts have been made to understand hurricane dynamics and improve hurricane track/trajectory forecasts. However, the complex mechanism by which hurricanes extract/dissipate energy at the air-sea interface is not fully understood. When hurricanes apply large wind stress at the air-sea interface, it enhances turbulent mixing below and increases the entrainment of cool water at the base of the mixed layer into the ocean mixed layer. Resulting sea surface temperature cooling, in turn, reduces air-sea heat fluxes that drive hurricanes. Recently, it has been found that upper ocean turbulent mixing may be significantly modified by surface ocean waves. Surface waves introduce net mass transport (Stokes drift) that interacts with turbulent eddies in a complex manner, depending on different wind and wave conditions (Langmuir turbulence). As a first step to investigate the Langmuir turbulence under hurricanes, the Stokes drift was determined for wave fields under stationary and translating hurricanes. The translating cases showed significant regions where wind and the Stokes drift were misaligned by more than 90 degrees, suggesting possible weakening of near surface turbulence due to surface waves. (Abstract ID 10001)

TOWARDS THE ABILITY OF THE ADJOINT TECHNIQUE TO RECOVER DECadal VARIABILITY IN THE NORTH ATLANTIC

The Atlantic Meridional Overturning Circulation (AMOC) has an important influence on today’s climate. However, continuous decadal-scale observations of the AMOC are not ongoing. Therefore, available ocean observations are assimilated into numerical ocean models to estimate the AMOC’s mean state and its variability. However, different data assimilation products show rather different AMOC mean states and variability. To understand these differences, we consider a reversed data assimilation approach. We evaluate the principle ability of the adjoint technique to reproduce a given AMOC from a controlled setup using identical twin experiments. Without observational uncertainties an artificial perturbation producing an AMOC change should in principle be detectable in space and time. We investigate how far deviations between model and synthetic observations can be minimized in the presence of artificial observational uncertainties, subsampling synthetic observations and non-linear effects, as e.g., convective adjustment. The results are used to assess error estimates of present assimilation products and AMOC hindcast simulations. (Abstract ID 11022)

A CLOSURE FOR SUB-MESO-SCALE PROCESSES IN THE OCEAN SURFACE MIXED LAYER

Linear stability analysis is used to construct a closure for sub-meso-scale eddy fluxes in the surface mixed layer. The linearized Navier Stokes equations using unstable mixed layer situations as basic state yield unstable wave solutions. The fastest growing mode of this eigenvalue problem is taken as representation for the vertical structure of the sub-meso-scale eddy fluxes -- i.e. in terms of diapycnal diffusivity and eddy streamfunction. Maximum growth rate and corresponding wave number of the fastest growing mode yield the magnitude of the diapycnal diffusivity and eddy streamfunction. A highly resolved mixed layer simulation is used to validate the parameterization by comparing the diagnosed eddy fluxes with their parameterized counterparts. It turns out that vertical structure and magnitude of the eddy fluxes are well captured. (Abstract ID 1029)

MARINE VIRAL SURVIVAL SKILLS: HOW OCEANIC MICROBIAL VIRUSES SUCCEED IN THE SOUTHERN OCEAN

Microbial viruses play vital roles in marine ecosystems, but little is known about their ecology and genomic content in polar environments. Here we investigate the roles of microbial viruses during the spring and summer in the highly-productive ocean near the Western Antarctic Peninsula. Ecologically, there was a substantial shift between seasons as bacterial abundance, bacterioplankton production and viral abundance increased sharply, while the percent of bacteria containing experimentally inducible temperate viruses decreased from 6-27% in spring to undetectable levels in the more productive summer. Comparative metagenomics revealed that springtime induced temperate viruses included significantly more siphoviruses and podoviruses than the free viral assemblage, while both summer metagenomes mirrored the spring temperate viral assemblage. This suggests selection for the temperate viral strategy to survive extended periods of low productivity. Further, functional annotation of the viral metagenomes revealed many transcriptional regulators and cold-inducible genes hypothesized to boost host fitness in this variably productive and low temperature environment. These preliminary results indicate that temperate viruses may play an important and previously unrecognized role in the microbial ecology of the Antarctic marine ecosystem. (Abstract ID 10666)

LARVAL CRASSOSTREA GIGAS GICALCIFICATION, BIOCHEMISTRY AND GROWTH: TOWARD AN ENERGETIC MECHANISM FOR ACIDIFICATION IMPACTS

Larval brachiopods are sensitive to decreases in pH and saturation state ($\Omega_{arag}$). The mechanisms for this sensitivity have not been fully described, in part because early shell formation is not thoroughly understood. We measured the elemental and isotopic composition of Crassostrea gigas larvae from fertilization to settlement size in a production hatchery setting. Larvae created inorganic shell and depleted organic carbon, including lipids, in the first two days, followed by an accumulation of lipid stores after the transition to more exogenous food sources. After 48 hours, bulk carbon partitioning was 68 % shell, with a maximum of 78 % by day five, followed by increasing organic:carbon. Carbon isotopes showed that inorganic shell mineral is primarily derived from DIC, with an increasing metabolic contribution in later larval stages following the reliance on exogenous food sources. We further distinguished between early shell layers with SEM imaging. These data highlight important links among ambient carbonate chemistry, energetic status, and early calcification in larval brachiopods. The energetic cost of initial shell development provides a clear mechanism for the susceptibility of early larval stages to ocean acidification. (Abstract ID 12599)

BARITE IN SINKING PARTICULATE MATER IN THE WATER COLUMN OF THE SOUTHERN ATLANTIC OCEAN

Marine biogenic particulate barium in form of barite is known to be a recorder of biologic productivity within the photic zone, since its formation is strongly linked to the decay of biogenic debris. The ratio of organic carbon and biogenic barium describes a characteristic decrease with depth. The barite content of a one year (1998-1999) sediment trap time series (3200 m depth) from a mooring site (31.76°S;176°W, 64.07°E;176°W) southwest of Bermuda within the Bermuda Atlantic Time-series Study area has been analyzed and compared with organic carbon flux at depth and satellite chlorophyll-a data. Discrepancies between the known organic carbon/biogenic barium ratios at different depths present in the western Atlantic Ocean and those ratios observed in sediment traps hint to interannual variability of barite precipitation in the western Atlantic Ocean. Furthermore, compiled biogenic barium and barite data of sediment trap material of two sites in the subtropical North Atlantic (31.76°S;176°W, 64.07°E;176°W and 33.00°S;176°W, 22.00°E;176°W) at different depth levels also imply spatial differences in the organic carbon/biogenic barium – depth relation between the eastern and the western study sites. OCEAN HEAT UPTAKE IN EDDY-RESOLVED AND EDDY-PARAMETERIZED CLIMATE SIMULATIONS

Will explicitly resolving ocean mesoscale eddies quantitatively alter projections of future climate change compared to projections in which the effects of mesoscale eddies are parameterized?
We address this question by comparing two experiments with the Community Climate System Model forced by a 1% per annum increase in the concentration of CO2. In the first experiment, the ocean component model has a nominal resolution of 1°, typical of contemporary coupled climate system models and includes a parameterization of mesoscale eddy mixing processes. In the second experiment the ocean component model has a resolution of 0.1°, thereby explicitly resolving the most energetic mesoscale eddies. In the control climate, both mean advection and vertical diffusion warm the deep ocean, while convection and mesoscale eddy fluxes cool the deep ocean. Under increasing greenhouse gases, the warming of the interior ocean is due primarily to a decline in the cooling by mesoscale eddies and convection. The model with parameterized eddies is able to capture the qualitative sense of the balances for both the control climate and transient climate change, but there are some quantitative differences. (Abstract ID 10663)

SENSITIVITY ANALYSIS, DATA ASSIMILATION AND UNCERTAINTY QUANTIFICATION IN OCEAN MODELING

To be successful and deliver products on schedule, an operational ocean modeling center such as the Naval Oceanographic Office (NAVOCEANO) follows a strict production routine. For each model, observations are collected, collated and quality-controlled; these data are assimilated; ocean model projects the initial conditions forward, and products are generated. Within this process, we need to quantify introduced errors and supply an estimate of output accuracy. At the “front end,” the Navy Coupled Ocean Data Assimilation (NCOEDA) system provides error indicators for the analysis fields. Through ensembling, multiple versions of a model are run create an output that can be used to determine model variability or uncertainty. Using a system called AutoMetrics, the Naval Research Laboratory (NRL) Stennis Space Center and NAVOCEANO are developing automated procedures to compare observations with forecast model fields. The collection and analysis of these comparisons can lead to estimates of model skill in both space and time. The ultimate goal is the addition of uncertainty fields that would accompany our forecasts of temperature, salinity, and currents. The presentation will show some examples of NCOEDA, ensemble, and AutoMetrics results; demonstrate how they are being applied by ocean forecasters; and discuss how uncertainty estimates are being introduced into the NAVOCEANO modeling runstream. NITRITE RESIDENCE TIMES IN THE PRIMARY AND SECONDARY NITRITE MAXIMA IN THE EASTERN TROPICAL PACIFIC: INSIGHTS FROM THE OXYGEN ISOTOPIC COMPOSITION

Nitrite is a central intermediate in the marine nitrogen cycle, and it is generally held in low concentrations in the ocean. However, nitrite accumulates at the base of the euphotic zone (primary nitrite maximum) and in the center of oxygen deficient zones (ODZs) in the secondary nitrite maximum. Here we introduce the idea of using static measurements of nitrite oxygen (O18) isotope signatures to quantify the rate of nitrite turnover. Three controlling factors were examined and used to estimate the residence time of nitrite. The oxygen isotopic composition of biologically produced nitrite was estimated using cultures of AOA and AOB, as well as natural seawater communities. Next, the rate and equilibrium isotope effect of abiotic O isotope exchange between nitrite and water were determined at a range of pH and temperatures relevant to seawater. These parameters, together with the isotope effects for nitrite oxidation and reduction were used to estimate the residence times of nitrite in the primary and secondary nitrite maxima in the Costa Rica Upwelling Dome and off the coast of Peru. ON THE SIZE DISTRIBUTION, COMPOSITION, AND SOLUBILITY OF PACIFIC OCEAN AEROSOLS

Between 2004-2006, 48-hour integrated aerosol samples were collected during three Climate Variability and Predictability (CLIVAR)-CO, Repeat Hydrography sections in the Pacific Ocean. Our size-fractionating cascade impactor was equipped with four sampling stages with aerodynamic diameter cut-points of 3.2µm, 1.0µm, 0.56µm, and 0.056µm. Twenty-three samples were collected in the North Pacific Ocean along 30°N (Section P02) and eleven were collected in the eastern Pacific Ocean along 150°W (Section P16). Ultrapure water extracts of the soluble fraction were analyzed by HR-ICP-MS. These samples were subsequently analyzed by EDXRF to measure the insoluble fraction. Data reported includes five GEOTRACES key parameters (Fe, Al, Zn, Mn, and Cu) as well as V, Ti, Pb and the major anions sulfate and nitrate. These data will be interpreted in conjunction with simultaneously collected bulk aerosol data. (Abstract ID 11291)

THE INFLUENCE OF SEASONAL NUTRIENT SUPPLY ON PHYTOPLANKTON BLOOMS IN A LOW-INFLOW ESTUARY

Drakes Estero, located in Point Reyes National Seashore, CA, is a low-inflow estuary (LIE). During the LIE season (July to October) nutrient supply to the estuary is via tidal fluxes from the adjacent ocean. During the non-LIE season (November to June) nutrients delivered via terrestrial runoff are likely to dominate. Additionally, oyster aquaculture may add to in situ concentrations. In May 2010 a study was initiated to investigate seasonal variation in nutrient supply and its potential influence on primary production. Measurements of nutrients, chlorophyll, primary productiation and phytoplankton nitrogen uptake, and phytoplankton species enumeration were made. During the LIE season a gradient of nutrient concentrations was observed with nitrate concentrations decreasing on the sea-to-land axis. The non-LIE season exhibited elevated ammonium concentrations at the landward end of the estuary. Throughout the year the DIN:PO4 decreased in the landward direction. Phytoplankton blooms occurred in the coastal and middle estuary during both seasons. This study will offer a mechanistic look at the consequences of seasonal variation in nitrogen sources on the phytoplankton ecology of Drakes Estero. (Abstract ID 12487)

THE ORGANIC COMPLEXATION OF DISSOLVED FE ON LEG 1 OF THE US GEOTRACES NORTH ATLANTIC SECTION

Dissolved Fe speciation was measured in samples collected from depth profiles in the NE Atlantic as part of the first leg of the U.S. GEOTRACES North Atlantic Section cruise. The speciation of dissolved Fe was determined using competitive ligand exchange-adsorptive cathodic stripping voltammetry (CLE-ACSV) with salicylaldoxime as the added ligand. A comparison of results between samples analyzed fresh at sea and analyzed back onshore after freezing and thawing showed excellent agreement, indicating that freezing samples at ~20°C is a suitable storage technique for dissolved Fe speciation samples. Strong Fe-binding ligands were found in excess of dissolved Fe concentrations at all depths in the profiles. Excess Fe-binding ligand concentrations (e.g., [L1-][Fe]) were found to vary with depth, with largest variations observed near the surface and in benthic boundary layers. (Abstract ID 9874)

EDDIES AS A SOURCE OF STRIATIONS IN TIME-AVERAGED SEA LEVEL ANOMALY

Eddies are investigated as the source of quasi-zonal patterns, or striations, in zonal geostrophic velocity (U) estimated from time-averaged sea level anomaly (SLA). Distinct four-year averages of SLA during 1993-2008 reveal striations in U1 which estimated from time-averaged SLA in the South Pacific (20°S–20°N) are characterized by speeds O(1 cm s-1), are separated meridionally by 200 km and appear to alternate in direction. Such patterns are similar to those observed in U1 which estimated from mean dynamic topography and Argo float measurements. Use of an eddy database in conjunction with a contour-identification and eddy removal algorithm demonstrates that quasi-zonal patterns are primarily the result of propagating eddies. Eddies account for 50−80% of the energy in the total observed U1 field and correlation coefficients between total observed and eddy-only U1 are 0.87–0.94. The latter illustrates that locations of striations match those created by eddies while the former allows for the existence of latent energy. Striations in sea surface temperature are also explored. Some attention is given to the abilities of the tracking and contour-identification/eddy removal algorithms to identify all eddy energy. (Abstract ID 10344)
COUPLED AIR-SEA-ICE MODELLING OF THE SVALBARD REGION

The Svalbard archipelago is an area of intense air-sea-ice interaction because the warm waters of the North Atlantic current meet the ice edge here. It is therefore a perfect evaluation region for a new coupled regional air-sea-ice modelling system. A new version of the Coupled Ocean-Atmosphere-Wave-Sediment Transport (COAWST) model which now includes sea ice dynamics and thermodynamics is used in the study. Model runs are performed covering the Svalbard fjords and surrounding continental shelves with special emphasis on the Storfjorden region. A large polynya occurs in Storfjorden every winter; a 10-20 km wide area of open water where intense sea ice formation and resulting brine water production take place. While an earlier modelling study using ROMS with sea ice reproduced some key polynya events, the results were largely dependent upon coarse-scale atmospheric re-analysis that had systematic errors due to orographic effects of the surrounding mountains. It is shown that the new model system captures the orographic effects important for amplifying and steering the wind field which generates an ice conveyor belt, thereby enhancing ice production. (Abstract ID 10620)

FIRST SEISMIC IMAGES OF THERMOHALINE STAIRCASES IN THE TYRRHENIAN SEA

We present the first seismically observed images of thermaline staircases in the centre of the Tyrrhenian Sea. The Tyrrhenian Sea is a deep, largely enclosed sea surrounded by a sharply grading continental shelf. Thermohaline staircases are well-defined, regular, step-like variations in vertical temperature and salinity gradients occurring in stable regions where temperature and salinity increase with depth compensating for density increases. They have been observed in the oceans. In response, we organized a research cruise in June, 2011 off Japan to study Fukushima-derived radionuclides in the waters and biota off Japan. This presentation will provide an overview of these successful sampling activities and our plans for analyses of a wide range of radionuclides. For this talk we will focus on the cesium-137 and cesium-134 surface distributions and vertical profiles obtained during this cruise. The highest cesium concentrations at that time were not necessarily at the closest sampling point 30 km from the Fukushima NPPs, but 70-100 km off shore. The data also suggests that the Kuroshio Current prevents the southward spreading of contaminated water. 134Cs/137Cs activity ratios (1.0 at source) indicate Fukushima-derived cesium out to at least 600 km off shore. These results are discussed in context of prior cesium levels in the waters off Japan and in comparison to radionuclide results from other studies in 2011 off Japan. (Abstract ID 10956)

DOUBLE RIDGE INTERNAL TIDE INTERFERENCE AND ITS EFFECT ON TURBULENT DISSIPATION IN LUZON STRAIT

Little is known about the tidal dissipation processes that occur at subcritical ridges of strong internal tide generation sites, such as the parallel West and East ridges in Luzon Strait in the South China Sea. In this study we investigate the location of the dissipation hotspots, the mechanisms of energy dissipation, and the effect of the double ridge structure and three-dimensional bathymetry on the dissipation. For this purpose, we apply the MITgcm
in both three-dimensional and two-dimensional configurations along zonal transects. In agreement with observations, the two-dimensional simulations show the dissipation is mainly due to turbulent lee waves. During semi-diurnal tides, the internal waves from both ridges are in phase, causing stronger dissipation, whereas during diurnal tides the internal waves destructively interfere, causing weaker dissipation. The effect of the three-dimensional bathymetry on this interference is considered with the three-dimensional model. Preliminary three-dimensional simulations show the barotropic flow is channeled around rather than across the steep sub-ridges, affecting the dissipation in magnitude and location. Dissolved nitrous oxide in the subsurface waters of the south atlantic ocean

Nitrous Oxide (N\textsubscript{2}O), an important greenhouse gas, is produced during nitrification and denitrification in the ocean interior. Full water column measurements of dissolved N\textsubscript{2}O were made in a pilot study along two recent sections in the South Atlantic as part of the global CLIVAR Repeat Hydrography/CO\textsubscript{2} Program. Dissolved N\textsubscript{2}O measurements were made on the same samples as for the anthropogenic tracers CFC-11, CFC-12 and sulfur hexafluoride. Dissolved N\textsubscript{2}O concentrations in near-surface waters were on average slightly above equilibrium with the atmosphere. Pronounced subsurface N\textsubscript{2}O maxima (2–6x atmospheric equilibrium) were present in upper waters, usually associated with high Apparent Oxygen Utilization. Deep and abyssal N\textsubscript{2}O concentrations were on average slightly above atmospheric equilibrium. Significant levels of the anthropogenic tracers were present in the N\textsubscript{2}O maxima, indicating decadal time-scale communication of these waters with the sea surface. These data can be used to estimate net N\textsubscript{2}O production rates. Including N\textsubscript{2}O measurements routinely on future CLIVAR cruises will allow the evolution of this signal in response to possible large scale changes in biogeochemical processes and ventilation in the global ocean to be determined. (Abstract ID 12366)

The effects of acute high pCO\textsubscript{2} exposure on growth and survival of Crassostrea gigas larvae

Water conditions during upwelling events are characteristic of ocean acidification, where atmospheric CO\textsubscript{2} absorbed into the ocean lowers the pH levels and changes water chemistry. This study demonstrated the effects of acute high pCO\textsubscript{2} levels on larvae of the Pacific oyster, Crassostrea gigas. The objective was to determine if acute exposure (24 hours) of the oyster's eggs to high levels of pCO\textsubscript{2} followed by exposure to optimal conditions had a detrimental effect on subsequent larval development. It was observed that eggs exposed to high pCO\textsubscript{2} for 24 hours had a higher percentage of abnormal larvae and a smaller shell width than eggs initially exposed to ambient seawater. It was also observed that both the percentage and total number of normal larvae increased in the high pCO\textsubscript{2} treatment during the 11 day growth period. This result suggests that batched abnormal larvae can survive and recover into normal individuals if subsequently raised under normal CO\textsubscript{2} conditions. A greater understanding of larval recovery and its implications may lend insight into the physiological processes occurring in response to exposure to high pCO\textsubscript{2}. (Abstract ID 9973)

Indian ocean salt transport using satellite observations and model simulations

In this study, we use salinity data from the Soil Moisture and Ocean Salinity (SMOS) mission, a 1/12° high resolution Hybrid Coordinate Ocean Model (HYCOM) and the Simple Ocean Data Assimilation (SODA) reanalysis to study salt transport in the monsoon-influenced Indian Ocean. Results show that the zonal component of the near surface salt transport was higher than the meridional component with the strongest seasonality observed along the Sri Lanka region while in the equatorial region it was almost entirely westward. Depth-integrated transport analyses indicate a northward transport of salt in bottom water layers and a southward transport of salt in surface layers. Salt transport generally increases southward with the highest transports occurring in the south (0°S–35°S) and a maximum at 30°S, a region influenced by the Circumpolar Deep Water and the Antarctic Bottom Water. EOF analysis show that the variability is primarily seasonally driven with the variability in currents being more important than the variability in salinity determining the long term variability in salt transport. (Abstract ID 9369)

Sources of strong copper-binding ligands in antarctic peninsula surface waters

Copper-binding organic ligands were measured during winter in surface waters of the Antarctic Peninsula using competitive ligand exchange adsorptive cathodic stripping voltammetry with multiple competition strengths. Samples were taken in four distinct water masses including the Antarctic Circumpolar Current, Southern Antarctic Circumpolar Current Front, Bransfield Strait, and the shelf region. Strong copper-binding organic ligands, known to be produced by cyanobacteria and diatoms, were detected in each water mass despite the minimum in biological activity. The strongest copper-binding ligands were detected at the highest competition strength in the Antarctic Circumpolar Current, with an average conditional stability constant of K\textsubscript{CuL,Cu} = 10^{4.5±0.5}. The weakest ligands were found at the lowest competition strength in the shelf region with K\textsubscript{CuL,Cu} = 10^{3.5±1.0}. No ligands with stability constants less than K\textsubscript{CuL,Cu} = 10^{-5} were detected in the ACC at any competition strength, suggesting a shelf source of weak copper-binding ligands. Free copper concentrations, the biologically available form, were less than 10\textsuperscript{-13} M in all samples, nearing levels that may be limiting for some types of indubile iron acquisition. (Abstract ID 10763)

On the relationship between warm water volume and el nino since 1955

At least since 1980, the "tilt" and the warm water volume (WWV) modes are the two most important modes of interannual variability in the equatorial Pacific. The tilt mode is approximately in phase with major ENSO indices, some of which are over 130 years long. By contrast, an annual-much WWV index exists only since 1980. The WWV mode leads the tilt mode by about a quarter of a period and it has been successfully used as a predictor of ENSO. However, in recent years, the lag between the indices has changed and predictions based on the WWV have failed. The main objective of this work is to find out if the lag between the tilt and WWV modes has changed also in the past. To investigate this, we constructed three monthly WWV index proxies which extend as far back as 1955 based on 1) in situ sea level and precipitation data, 2) NOAA gridded heat content data and 3) SODA-POP (Simple Ocean Data Assimilation) temperature profiles. We found that before 1980, the sea-level-based and the SODA indices show a clear reduction in the lag of best correlation with Nino3.4 The lag reduction is associated with the highest correlation with Nino3.4 over the whole record, suggesting that before 1980, in the present, the relative importance of the WWV mode with respect of the tilt mode had decreased. Propagation features of decadal-scale subsurface signals in the north pacific ocean

The Kuroshio Extension supports both eastward and westward moving subsurface signals. These signals are important in regulating low-frequency air-sea interactions in the region. Typically studies of sea surface height anomalies report westward propagation and interpret these as Rossby waves, while investigations of upper ocean heat content find eastward propagation and cite mean flow advection as an underlying cause. Yet, heat content in general affects the velocity field and also evolves as a Rossby wave. We investigate this dichotomy using a 150-year CGCM integration and a 60-year eddy-resolving OGCM integration. Our analysis demonstrates the following. The signals associated with the first baroclinic mode are governed by the non-interaction theorems and propagate westward largely independently of the mean flow. The eastward-propagating signals are a mixture of higher baroclinic modes and density-compensated temperature and salinity anomalies. The result suggests that the commonly used indices of heat content of the upper ocean result from a mixture of different dynamics and vertical structures. (Abstract ID 11411)

Inter-annual variations in temperature, salinity and oxygen off Wallops Island, VA

Human induced global warming has already started causing physical and biological impacts on both global and regional scales (IPCC, 2007). What is more troubling is that such impacts are occurring earlier and faster than scientists have predicted. The Mid-Atlantic Bight (MAB) shelf waters are one of the most productive in the world (Yoder et. al., 2002). However, the mid-shelf region of the MAB has some of the most stratified continental shelf waters and encompasses the location of the 1976 Anoxic Episode, where intense stratification was one important element of the synergism resulting in anoxia and extensive fish/shellfish mortalities (Campbell & O'Reilly, 1988). In this week we will analyze CTD data sampled off Wallops Island, VA from
2001 to 2011 and archived at the Marine Science Consortium, Wallops Island, VA. We will look at inter-annual trends in the temperature and salinity anomaly fields and relate them to oxygen data collected in the same region. The goal of this work will be to identify stratified regions and understand the variation of oxygen in these regions. (Abstract ID 11252)

Carruthers, T. J. and L. Latasa, University of Plymouth, Plymouth, UK. To determine the rate and ratio of particulate organic matter remineralization by natural microbial populations

Recent studies of elemental stoichiometry of particulate and dissolved organic matter show large departures from Redfield trajectories driven by alterations in phytoplankton species composition, the molecular composition of organic matter and preferential remineralization of N and P by heterotrophic bacteria. The stoichiometric and molecular composition of photosynthetic microorganisms can control the rate and extent of remineralization, and thus, the recycling efficiency of oceanic systems. To investigate this process, we have harvested POM of variable and known molecular and elemental composition from cyanobacterial (TribacodesiumIMI101 and Prochlorococcus MED4) and eukaryotic cultures (Thalassioea pseudonana). We have introduced this material to natural heterotrophic bacterial populations collected in the oligotrophic North Pacific Subtropical Gyre and the upwelling regime off the Oregon coast and tracked the stoichiometric transformation of organic nitrogen and phosphorus to particulate (bacterial) and inorganic pools in both short (days) and long (months) term experiments. Ultimately, the rate and ratio of particulate matter remineralization derived from these experiments is relevant to the relationship between production and consumption of N and P in the open ocean. CONSEQUENCES OF RESTRICTED GENE FLOW ACROSS A BROAD GEOGRAPHIC RANGE: OUT-BREEDING DEPRESSION AND LOCAL ADAPTATION IN AN INTERTIDAL COPEPOD

The intertidal copepod Tigriopus californicus exhibits restricted gene flow and extensive population divergence across its geographic range. Two important consequences of restricted gene flow are evident in this system. First, laboratory crosses show that genetic incompatibilities have evolved between populations resulting in reduced fitness of interpopulation hybrids (hybrid breakdown or out-breeding depression). Current evidence indicates that a primary mechanism underlying hybrid breakdown in this system is the disruption of interactions between nuclear and mitochondrial genes. Transcription of mtDNA appears to be reduced in hybrids due to population divergence between the mtDNA control region and the nuclear-encoded mitochondrial RNA polymerase complex; reduced transcription results in mitochondrial dysfunction and poor fitness. A second consequence of restricted gene flow is that populations have evolved differences in thermal tolerance consistent with their local environments. Using a RNA-seq approach, we observed marked population differences in gene expression across the transcriptome in response to acute thermal stress. Levels of up-regulation of heat shock genes were significantly higher in the thermal tolerant southern population compared to the more sensitive northern population suggesting local adaptation in gene expression. CO-VARIATION OF INTERTIDAL MORPHOLOGY, BEDFORMS AND GRAIN SIZE ON A MACROTIDAL SAND BEACH: PRAA SANDS, UK.

To better understand the gradients in sediment transport on beaches, a 3-week experiment was carried out in May 2011 at Praa Sands, a steep energetic macrotidal beach in Cornwall, UK. Waves, currents, suspended sediment concentrations, and bed elevations/
bedforms were measured in a cross-shore and alongshore array across the sub-tidal and intertidal beach face. As well as repeat bathymetric surveys, a novel aspect of the experiment was the density of grain-size measurements, using a bed-sediment camera system for spatial surveys, and a wave-powered sediment camera to provide a time-series of sediment images under the waves. Bed sediment grain-size was highly variable. Sediment fining coincided broadly with areas of net accretion over individual tides, and coarsening with net depletion: a pattern more readily apparent during quiescent periods. We examine the effects of changes in grain size on morphological development, in the light of sediment transport models fed with accurate grain size information. In addition, grain-size changes are used to understand observed transitions between flat-bed and rippled bed states, and to assess the performance of ripple predictors. (Abstract ID 10168)

DEVELOPMENT OF A MOORING BASED IN-SITU CALIBRATION SYSTEM FOR AANDERAA OXYGEN SENSORS

Oxygen-based mass balance estimates of biological carbon export require accurate in-situ O2 measurements. Aanderaa optodes are more stable than Clark electrode style sensors but still exhibit some drift and require extensive initial calibration. Aandreaa optodes measure the pO2 in a medium and have been shown to work in both air and water. We have developed an in-situ calibration system using atmospheric air as a standard. The optode is housed on the mooring in a subsurface chamber and regularly exposed to ocean water during normal sampling. During each calibration period, pumped atmospheric air displaces air from the optode housing, which is then sealed. The pressure and temperature of the air inside the housing is measured, allowing calculation of the pO2. Comparison of the calculated pO2 to the optode measurement of the isolated air allows calibration of the optode. Lab experiments calibrating optodes in both air and water validate this method of in-situ calibration and indicate that the presence or absence of an optical isolation layer on the optode face may impact the measurement in air. LABORATORY STUDIES OF GROWTH AND GRAZING

Large blooms of symbiont-containing green Noctiluca scintillans have recently become more common in the Northern Arabian Sea. Experiments were performed to determine the relative importance of light, nutrients and heterotrophy to the growth of these green Noctiluca scintillans. Green Noctiluca scintillans incubated in filtered ambient Arabian Sea water grew faster in sunlight compared to those held in the dark, and even faster when f/20 levels of inorganic nutrients were added. When green Noctiluca scintillans were incubated with a concentrated natural food assemblage, growth rates were similar to cells in light with added nutrients. Faster division rates resulted in smaller cells and only a slight increase in biomass. The growth rates of the "green" symbiont-containing Noctiluca scintillans were also compared to the "red" strictly heterotrophic Noctiluca scintillans found on the Texas coast. Green Noctiluca scintillans generally grew faster than red Noctiluca scintillans at low food concentrations (below 0.1 mg C per liter), but slower than red Noctiluca scintillans at high food concentrations. The only zooplankton grazers that were observed to feed on Noctiluca scintillans in the Arabian Sea were salps, which appeared in dense patches within the bloom area. (Abstract ID 9754)

Noctiluca scintillans after the Hebei Spirit oil spill on the west coast of Korea

In order to assess the short-term effects of the oil spill on phytoplankton and crustaceans, their condition, reproductive activity, and biochemical composition were investigated from August 2009 to October 2010 after the Hebei Spirit oil spill at Malipo (OS) on the west coast of Korea. No significant differences were found in water temperature and food indices between the two sites. At an adjacent control (CS), dry tissue weight (DW) of a standard animal remained at low levels in late summer and increased throughout the autumn–winter, peaking in spring, when protein and carbohydrate were at highest levels, and followed by a sharp decline throughout the summer. In contrast, although DW recorded a weak peak in July, no seasonal fluctuation was found at the OS. Maximum values of all the biometric components at the OS did not exceed the winter values at CS. Histological observation showed a seasonal cycle in gametogenic development, gonad maturity index peaking in summer in both sites. Egg weight (EW) was much higher at the CS than at the OS in June–July. The EW peaked in June at the CS and July 1-month later at the OS. The EW dropped in July at both sites, indicating spawning of the oysters. Our results demonstrated that despite a similarity in environmental condition, between-site difference in gross values of the biometric components of the oysters are likely to reflect the effects of the oil spillage on the phytoplankton 2–3 years after the accident at the OS. (Abstract ID 11113)
OCEANIC DYNAMICS ASSOCIATED WITH ENSO IN AFFECTING THE SST VARIATION IN THE WESTERN PACIFIC/PHILIPPINE SEA SECTOR

During the warm phase of El Niño-Southern Oscillation (ENSO), sea surface temperature (SST) in the western Pacific/Philippine Sea sector exhibits anomalous cooling. Compared to the warm anomalies in the eastern Pacific, the magnitude of the cooling is relatively small (0.2-0.7°C), yet the impact on the regional climate is significant. It is found that the correlation between the interannual variations of net heat flux and SST tendency is weak in the tropical western Pacific, and that the Philippine Sea generally receives positive surface heat flux during El Niño. The involvement of oceanic dynamics in generating the cold SST anomalies has been proposed, but the actual oceanic processes are not clear. The oceanic variability of this region associated with ENSO is investigated using data from the three dimensional, eddy-resolving Ocean General Circulation Model for the Earth Simulator (OFES). The 1997/98 El Niño event is chosen as an example. OFES results indicate that the dynamical process of the thermocline upwelling in this region involves both the local effect related to the current variability and non-local waves. The thermocline variation is essential for producing strong and large cooling off the equator in the Western Pacific while the contribution of vertical entrainment is mostly important. LONG-TERM DEVELOPMENT OF HYPOXIA IN THE BALTIC SEA COASTAL ZONE

The Baltic Sea has the largest area on the globe with eutrophication-induced hypoxia averaging 49,000 km² over the last 50 years. In addition, we have identified 115 sites that have experienced hypoxia during the period 1955-2009 increasing the global total to ca. 500 sites. Some of the most severe hypoxic conditions are in the South Baltic and the Gulf of Bothnia, and these regions are the subject of the present study. Several sites in the southern and western Baltic Sea have experienced hypoxic conditions since the 1950s, and these sites have been selected for detailed analysis. The study will assess the causes of hypoxia and the impact on the ecosystem, and will address the potential for recovery from hypoxia. (Abstract ID 16767)

How does the Mesoscale Eddy-Driven Current in the South China Sea Affect Coastal Ecosystems?

The Mesoscale Eddy-Driven Current (MEDC) is a prominent feature of the South China Sea (SCS) circulation, characterized by the presence of eddies that rotate along the SCS coastline. These eddies play a crucial role in the transfer of heat, salt, and nutrients, influencing the biological productivity and ecological processes in the region. The study aims to investigate the dynamics of the MEDC and its impact on the coastal ecosystems, focusing on the interannual variability and the influence of environmental factors. WIND MEDIATED EDDY DEFORMATION AND EDDY CONFINEMENT IN THE WAKE OF A MOUNTAINOUS ISLAND

Madeira Island mountains are known to induce the occurrence of atmospheric wakes manifested with the formation of Von Karman Vortex Streets. Oceanic eddies are also frequently observed. Using a two-dimensional, simplified numerical model, a wind stress term was introduced in the quasi-geostrophic equation. Constant and variable wind was superimposed on an oceanic channel with neutral side boundaries, prescribed inflow, and radiation outflow conditions. Results showed that the generation of oceanic vorticity, at the island's flanks, contributed to the increase of oceanic vorticity. Variable wind contributed to the asymmetry of successive eddy-shedding periods. Wind forcing over the open-ocean, continued to contribute to oceanic eddy asymmetry as well as to progressive eddy deformation. In the open-ocean, wind also helps confine eddies onto a corridor. For the no eddy-shedding wake regime (weak oceanic Re), wind forcing strongly contributed to the stretching of the ocean 'jet-like' features, consistent with the Swedrup transport theory. Realistic numerical experiments using the Regional Ocean Modeling System (ROMS), forced by the Weather and Research and Forecasting model (WRF), showed that the use of high-resolution winds contributed to the generation of local oceanic vorticity. As suggested by the idealized numerical experiments, eddies were also aligned with the wind-induced wake. Cycliconic and anticyclonic eddies revealed different response to the atmospheric wake. VARIE D DEPENDANCE OF EDDY DEFORMATION RESULTS AND IMPLICATIONS FOR WIND-CAPED Eddy DEFORMATION PARAMETERS AND SCATTER
Whitecap coverage (W) parameterizations have been used to estimate the transfer velocity of CO2 and to predict the production of primary marine aerosols. W scales with wave energy dissipation, and is often represented in terms of wind speed. Historical measurements of W exhibit 3 orders of magnitude of scatter, some of which is probably due to variation of measurement technique. Recent measurements of W exhibit less scatter, but still vary by about a factor of 10. Here we explore the possibility that some of this scatter is driven by variations in whitecap foam decay rate, which is usually assumed to be constant. An analysis of foam decay rates observed off Martha's Vineyard over the course of several days will be presented. The area of individual whitecaps is observed to decay quasi-exponentially, with decay constants ranging from 0.5 to 8 seconds. Foam decay rates vary with breaking wave intensity. However, ensemble averages across a range of event intensities on different days also show statistically significant variability. The implications of this result for the observed variability in whitecap coverage will be discussed. (Abstract ID 11497)

PREDATOR INDUCED HATCHING-PLASTICITY IN NUDIBRANCH SPECIES ARMINA CALIFORNICA
Predator induced hatching-plasticity has been recently demonstrated in a few species of marine organisms. This phenomenon has increased our knowledge of understanding life cycles. To continue this trend a species of nudibranch, Armina californica, was collected and tested for the presence of hatching plasticity when egg masses were chemically exposed to a possible predatory subtidal shrimp. Shrimp were placed in small buckets on a sea water table with continuous water flow into the buckets. Egg masses were split into four equal pieces with two assigned predator present treatments and two with predator absent, and then placed in tea strainers within the buckets. Results found that exposed to predator present chemical cues embryos would accelerate their hatching time by an average of 2.2 days compared with embryos not exposed to predators. This is consistent with expected adaptive response. Future work could be done to examine embryo size and number, and during experiment observations suggest that species possibly exhibits intercapsular cannibalism. (Abstract ID 12899)

CHANGES IN COMPOUND SPECIFIC 15N AMINO ACID SIGNATURES AND D/I RATIOS IN MARINE DISSOLVED ORGANIC MATTER INDUCED BY HETEROTROPHIC BACTERIAL REWORKING
Stable isotopes are powerful tools for following the flow of carbon (C) and nitrogen (N) through biogeochemical processes in marine ecosystems. Marine dissolved organic matter (DOM) is one of the largest reservoirs of reduced nitrogen and carbon on earth, however its sources and reactivity still remain poorly understood. Stable carbon (δ13C) and nitrogen (δ15N) isotopic analysis of individual amino acids (AA) are rapidly developing as important new tracers for differing DOM autotrophic sources. However the influences of direct cellular AA excretion and, in particular, of heterotrophic bacterial degradation on δ15N-AA patterns are critical, but poorly constrained, factors. We tested differences in δ15N signatures of individual amino acids from DOM freshly produced by autotrophic sources vs. changes after heterotrophic bacterial reworking, comparing both to signatures of corresponding fresh algal biomass. The degradation results were also contrasted with changes in enantiomeric ratios of the same amino acid pool. Together, our results suggest that δ15N-AA patterns coupled to D/L ratios constitute a new approach elucidating microbial effects on long-term preservation of DOM in the water column. SELF-INDUCED SHEAR FLOWS BY INTERNAL WAVES
Internal waves moving in stratified fluids generate their own shear flows that can become unstable to Kelvin-Helmholtz roll-ups for sufficiently large amplitudes. This talk will present a combined theoretical and numerical study of this instability starting with the spectral analysis of the corresponding non-self adjoint Taylor-Goldstein equation for parallel shears. Mode evolution in this set-up, and in particular non-normal mode growth and/ or decay in addition to true spectral instability, helps explain some of the features observed in a numerical study of internal wave propagation. In particular, the talk will present results on how perturbations in the path of large internal solitary waves with pockets of unstable shear flow at their peaks trigger instabilities, and how these waves can in fact act as suppressors of disturbances by entraining their energy into the main flow. (Abstract ID 10633)

LONG-TERM BENTHIC BOUNDARY LAYER MONITORING AT THE MISSISSIPPI CANYON BLOCK 118 HYDRATES OBSERVATORY
Since 2006 an experimental seafloor mooring, the benthic bottom layer array (BBLA), has been repeatedly deployed in the Northern Gulf of Mexico at the Mississippi Canyon Block 118 hydrate observatory site. The BBLA is a modular, fully self contained observatory node that can be relocated using a ship and hydro wire. It is designed to operate on less than two Watts for durations of up to one year. This hydrate observatory node provides a baseline for studying natural temporal variations in benthic water column chemistry associated with the Woodsey Mound cold seep site. Located less than 10 nautical miles from the Macondo well, the ongoing BBLA deployments provide a comparative baseline of pre and post-spill benthic water column chemistry, including hydrocarbon levels. We present an overview of the Woodsey Mound cold seep site and BBLA deployment results, along with an outline of the BBLA architecture, and an introduction to innovative technologies that are significantly extending its operational endurance. USING EXCITATION EMISSION SPECTROSCOPY TO ASSESS THE POTENTIAL IMPACT OF RIVERINE DISSOLVED ORGANIC MATTER ON BIOGEOCHEMICAL PROCESSES
Climate change is expected to alter the delivery of terrestrial organic matter (OM) and nutrients to downstream aquatic environments. Here, the sources and composition of OM exported from forested and wetland sub-environments within Tiакinas Creek, Virginia (USA) were compared during base-flow and storm flow conditions using excitation emission spectroscopy (EEMS) combined with hydrologic monitoring and measurement of the fluxes of nutrients and dissolved organic nitrogen and carbon. Stable isotopic composition of stream particulate OM was compared to end-members of terrestrial and wetland sources to serve as an additional identifier of OM sources. DOM reactivity was assessed using microbial, photochemical and nutrient addition experiments for surface water that was exported. Preliminary data indicate that base-flow samples from both the forest and wetland sites have a combined terrestrial and microbial source, with wetland DOM collected during baseflow containing more soil-derived terrestrial DOM. The composition and flux of DOM are expected to differ during baseflow and storm flow and between forested and wetland environments, which will lead to variability in the reactivity and impact of DOM exported to downstream aquatic systems. (Abstract ID 11448)
Our goal is to understand the impact of changing sea-ice conditions on planktonic food web dynamics during spring sea-ice conditions. F., Oregon State University, Corvallis, OR, USA, sherrb@coas.oregonstate.edu

The increasing occurrence of harmful algal blooms (HABs) has prompted studies aimed at determining biotic and abiotic factors which may promote bloom initiation, maintenance, and decline. Although many studies have tried to evaluate the effectiveness of "top-down" or "bottom-up" control of HABs, there is evidence to support both mechanisms. Protozoan grazers are likely candidates for "top-down" control of HAB species since they have the potential to increase their populations at growth rates similar to those found for many HAB species. However, it is difficult to determine if protozoan grazers are feeding on HAB species based on microscopic observations alone. PCR amplification of genetic material, focused on a species- or genus-specific HAB gene, will more precisely determine if an individual grazer has ingested a HAB species during controlled grazing experiments; these results can then be tested in natural grazer assemblages. Long-term grazing experiments will show whether a particular grazer can be an effective "top-down" control of a HAB species. The dinoflagellates Noctiluca scintillans and Protoceratium sp. are the grazers included in this study. (Abstract ID 10251)

USING PARTNERSHIPS TO INCREASE DIVERSITY IN THE OCEAN SCIENCE WORKFORCE: NC OPT-ED AND COSEE SE

The North Carolina Alliance to Create Opportunity Through Education (NC OPT-ED) involves statewide institutions that are committed to diversifying the science, mathematics, technology and engineering workforce, including the professorate. NC OPT-ED collaborates with educational programs at all levels (K-16 and graduate) to recruit, mentor, and graduate underrepresented minority students from STEM doctoral programs. In December 2010, NC OPT-ED participated in a workshop hosted by the Center for Ocean Sciences Education South East and NC State University designed to form regional partnerships and action plans for activities that would increase diversity in the ocean sciences workforce. As a direct result of that workshop two NC ocean scientists were invited to present on marine science careers at the 10th Annual NC OPT-ED Alliance Day, reaching over 500 middle and high school students. Establishment of partnerships between existing collaborative networks whose common goal is increasing diversity in STEM fields can dramatically increase the number of students exposed to the ocean sciences. LINKING MELTING ICE TO VARIABILITY IN THE COPPER RIVER PLUMES AND COASTAL GULF OF ALASKA

The Copper River is the largest point source of freshwater to the northern Gulf of Alaska, and the coastal ocean is connected hydrologically, biogeochemically and biologically with the upwelling systems of the watershed. The Copper River watershed (and much of southeastern Alaska) is heavily glaciated, and losses in ice mass have been documented in recent decades. The freshening trend in the surface ocean from meltwater has lead to myriad changes in the Alaska Coastal Current. Using historical data, and the results of recent COASTAL GULF OF ALASKA

FEEDING AND REPRODUCTION OF MESOZOOPLANKTON IN THE BERING SEA DURING SPRING SEA-ICE CONDITIONS

Our goal is to understand the impact of changing sea-ice conditions on planktonic food web structure and function by describing mesozooplankton and microzooplankton trophic linkages and the fate of phytoplankton blooms in the Bering Sea during spring. During three research cruises in 2008, 2009 and 2010, as part of the BEST-BISERP program, we conducted experiments with dominant mesozooplankton to determine feeding rates on phytoplankton, ice-algae, and microzooplankton. Most mesozooplankton exhibited a saturating feeding response to increasing chlorophyll concentration. All species were found to be omnivorous: some had a strong preference for microzooplankton, while others exhibited no strong preference for any prey type. Based on enriched treatments with ice-algae, it appeared that most could significantly increase their ingestion rates by feeding in close association with the ice. Overall, mesozooplankton grazing-impacts appeared to be minimal at most bloom locations. Egg production rate (EPR) experiments with productively active copepod species were also conducted. The EPR of Calanus spp. in early spring was asymptotically related to both ingestion rate and ambient food concentration, indicating that reproduction depended on ingested food. (Abstract ID 12700)

SIMULATING THE ADIABATIC INTERIOR OF THE SOUTHERN OCEAN WITH AN EDDYING Z-COORDINATE MODEL

Southern Ocean (and North Atlantic) tracer release experiments have confirmed that the ocean interior, below the surface mixed layer and away from rough bathymetry, are predominantly adiabatic, with low diapycnal mixing rates. At the same time mesoscale eddies are actively stir and mix tracers along tilted neutral surfaces. Maintaining appropriately low levels of diapycnal mixing has proved challenging for z coordinate ocean models, particularly in eddying regimes. Mesoscale eddies are associated with frontal processes and steep isopycnal slopes. Unless care is taken, this can lead to spurious diapycnal fluxes in z-coordinate models. Here we use several metrics that quantify the rate of spurious mixing implied by advection schemes commonly used in ocean models. We demonstrate that a second-order moment (SOM) scheme based on the work of Prather results in physically acceptable diapycnal mixing (i.e. below 10^{-3} m^2/s). In particular, as a consequence of improved adiabatic interior, the diagnosed residual-mean overturning circulation now aligns with neutral surfaces and allows fluid parcels to rise from the interior to the surface without the need to invoke strong diapycnal processes. Climatic implications are further illustrated by use of various tracers (surface age tracers and point-wise tracer releases mimicking tracer field experiments). (Abstract ID 10688)

TRENDS IN MOC AND MERIDIONAL HEAT TRANSPORT IN THE SOUTH ATLANTIC IN A NUMERICAL EXPERIMENT WITH HYCOM FOR 1960 – 2010

A 1/4-degree implementation of HYCOM, with 22 hybrid layers, was forced with monthly means of NCEP reanalysis for the period 1948-2010. The results show a positive trend in sea surface temperature and salinity in the subtropical South Atlantic, in the period from 1970 to 2010. Possibly as consequence of changes in the westerlies, the model presents a poleward shift of the zero-line sea surface height in the Subtropical Front, near the Agulhas retroflection, suggesting a widening of the connection between the South Atlantic and Indian Ocean. The results also show a negative trend in the meridional overturning circulation and meridional heat transport across different latitudes in the South Atlantic. (Abstract ID 10734)

ADVANCING THE CARIBBEAN COASTAL OCEAN OBSERVING SYSTEM

Prior to the implementation of the Caribbean Coastal Ocean Observing System (CarICOOS), real-time observations of basic oceanic variables such as waves and currents were nonexistent in the US Caribbean, making it arguably the most under-observed coastal region in the US. Since its inception in 2006, the design of the CarICOOS observing system has been based on sector-focused needs assessment and consultation with stakeholders. Such consultations highlighted the need for operational instrumented buoy platforms to provide data on winds, waves, currents and water quality. It was also concluded that given the difficulty and expense of deploying such platforms, the number of assets should be optimized to provide representative coverage at key locations in the PR / USVI archipelago. In addition, a suite of numerical models of winds, waves, currents and storm surge are currently being implemented for the region and validated with observation data from the CarICOOS buoy network.
with our observational assets. In this presentation we outline our current status and present our five year plan to further advance and ensure the long-term success of the Caribbean Coastal Ocean Observing System. (Abstract ID 12891)

CLIMATE CHANGE IMPACTS ON THE ORGANIC CARBON CYCLE AT THE LAND-OCEAN INTERFACE

The anticipated effects of climate change on estuaries are likely to be both numerous and complex. A key function of estuaries is the transfer and transformation of carbon and biogenic elements between land and ocean systems. Climate change has the potential to influence the carbon cycle in estuaries through anticipated changes to oceanic matter production, transformation and export. Estuarine biogeochemical processes will likely be altered by: 1) sea level rise and increased storm intensity which will amplify the erosion and transfer of terrigenous materials, 2) increases in water temperatures which will enhance the rates of biological and biogeochemical processes (e.g., enzyme kinetics, decomposition rates, and remineralization), while simultaneously decreasing the concentration of dissolved oxygen, 3) changes in particle (or sediment) loadings in response to altered patterns of precipitation and river runoff, and 4) altered inputs of nutrients and dissolved organic material to coastal waters, also resulting from changing precipitation and runoff. In this presentation, we review the effects of climate change on the cycling of carbon in estuaries, with a focus on the temperate estuaries of North America. (Abstract ID 9907)

THE RELATIONSHIP BETWEEN SURFACE METEOROLOGICAL OBSERVATIONS AND MODES OF CLIMATE VARIABILITY IN THE LARSEN ICE SHELF SYSTEM, ANTARCTICA

Rapid regional warming over the northeast Antarctic Peninsula in the last fifty years is thought to have contributed to the retreat and disintegration of the Larsen A and B ice shelves. While recent laboratory and modeling studies have linked increases in summer temperatures to the positive trend in the Southern Annular Mode (SAM) climate index via the strengthening of the circumpolar westerlies, field data to test these hypotheses have generally been lacking. As part of the LARISSA (LARsen Ice Shelf System, Antarctica) project, we analyzed data from long-term weather stations as well as additional ground stations adjacent to the Larsen B embayment to explore the response of near-surface meteorological conditions to changes in climate indices. Preliminary field results indicate that increases in SAM are indeed associated with increased wind velocity and temperature as well as decreased surface air pressure leading to favorable melt conditions, as proposed by models. Foehn (downslope, warm) wind events were also significantly more frequent during periods of positive SAM. Such conditions may have large impacts upon the surface temperature of the newly opened Larsen B embayment. (Abstract ID 12670)

CARBON FIXATION AND PHOSPHORUS TURNOVER IN SURFACE WATERS OF THE EASTERN TROPICAL SOUTH PACIFIC (ETSP)

Rates of inorganic carbon uptake and phosphate turnover were determined on a cruise in the ETSP during Mar & Apr 2011 at several stations on transects along 10oS and 20oS, from the seaward end of the southern transect. Similarly, phosphate turnover was most rapid (~0.08 h-1) at the seaward end of the northern transect and lowest (1.56 h-1) at the northern transect for the first couple of decades after the diversion. By the 1950s alterations to the supply of sediment initiated a regressive stage of delta development, and a hurricane in 1961 deflected the delta westward creating the asymmetric sub-aqueous delta. Asymmetric progradation created a broad shoal to west where wave action is dampened allowing for sediment accumulate at rates of -2 cm/yr. East of the river mouth, where the supply of sediment is now reduced, sediment deposited rapidly during the initial phases of progradation have been reworked and transported across the shelf to deeper water away from the delta. RECONSTRUCTING THE LIFE OF A PELAGIC SHARK USING STABLE ISOTOPE ANALYSIS

Salmon sharks (Lamna ditropis) are wide-ranging apex predators in the North Pacific. As apex predators they likely play an important role in North Pacific marine ecosystems, yet virtually nothing is known about how habitat use and trophic ecology shifts during ontogeny. We used
stable isotope analysis (SIA) of salmon shark vertebrae to elucidate ontogenetic changes in habitat. The tissue in each annulus of a salmon shark’s vertebrae provides an isotopic record that reflects movements and foraging integrated over a year of a shark’s life. By serially sampling vertebral annuli for stable isotope ratios of carbon (13C/12C) and nitrogen (15N/14N) we were able to reconstruct ontogenetic changes in habitat use for individual sharks. We used a basic isoscape characterizing the major biogeographical provinces of the eastern North Pacific to estimate use of different regions. Electronic tagging data were used to infer SIA results by characterizing annual patterns of ecoregion residence. Integrating electronic tag and stable isotope data provides a unique and powerful way to study the ecology and life history of these important and difficult to study predators. (Abstract ID 12427)

Carlotti, F., C.N.R.S. /Université de la Méditerranée, Marseille, France, francois.carlotti@univmed.fr

The influence of hydrodynamic processes on zooplankton transport and distributions in the North Western Mediterranean sea estimated from a Lagrangian model. A Lagrangian module has been developed and coupled with the 3D circulation model ‘Symphonie’ to study the influence of hydrodynamic processes on zooplankton transport and distributions in the North Western Mediterranean Sea. We simulate the trajectories of passive and vertically migrating zooplankton within in a domain extends between longitude 1.5°W and 10.9°E and latitude 38.28°N and 56.1°N. In order to classify different zones of the NWM as aggregative or dispersive, we divided the model domain into 9 sectors. The model is firstly used in forward procedures to study teleconnectivity between different regions of the NWM sea. The individuals are released from March to October from different places of the NWM and tracked for 40 days either as passive zooplankton or with a simple diel vertical migration (DVM) pattern. Then, the model is used in backward procedure to study the origin of organisms drifted to the coastal line all around the NWM sea. This backward procedure is particularly interesting to investigate the patterns of distribution of the jellyfish Pelagia noctiluca from areas where coastal jellyfish invasion have been observed, on the French Riviera, the Gulf of Lions and the Catalan and Balearics seas. The simulations offer a tool to suggest potential pathways of jellyfish transports in the NWM sea. (Abstract ID 9684)

LONG-TERM ACCUMULATION OF DOC IN THE UPPER LAYER AT BATS The stock of dissolved organic carbon (DOC) experiences regular annual patterns of euphotic zone build-up, redistribution and export due to mixing and net remineralization within the mesopelagic zone at BATS. Imprinted on the annual periodicity of DOC has been a significant long-term trend in which >1 mol / m2 DOC has further accumulated within the surface 800 m. Throughout the BATS time series record there have been multi-year periods where the annual maximum mixed layer depth has systematically shifted to less than 200 m during which net DOC accumulation has occurred within the euphotic zone. The formation and delivery of DOC-enhriched subtropical mode water also appears to be an important contributor to the accumulation observed in the mesopelagic zone. We will discuss the local and advective processes that affect the long-term trends in DOM accumulation in relation to previous data illustrating how DOM character is altered in time and space within the surface layer at BATS. (Abstract ID 10586)

Caron, D. A., University of Southern California, Los Angeles, CA, USA, dcaron@usc.edu

LOW TEMPERATURE CONSTRAIN GROWTH RATE BUT NOT GROWTH EFFICIENCY OR INSTANTANEOUS GRAZING RATE OF ANTARCTIC MICROZOOPLAGNKTON Low environmental temperature has a significant, but still poorly quantified effect on the ingestion rates, growth rates and gross growth efficiencies of herbivorous polar microzooplankton. These features were investigated in field and laboratory experiments involving cultured isolates and natural communities from the Ross Sea, Antarctica. Ingestion rates of natural microzooplankton assemblages determined by the uptake of fluorescently labeled algae were low in field experiments relative to rates reported for clustics from temperate environments. However, instantaneous ingestion rates of the Antarctic ciliate, Strombidium sp., in laboratory experiments conducted at low temperature varied greatly with physiological state. Strombidiumvaried prior to exposure to high prey abundances had instantaneous specific ingestion rates significantly higher than ingestion rates of the same species measured during balanced growth. Low temperature constrained digestion but apparently not instantaneous ingestion rates. Growth efficiencies were markedly decreased by low temperature. These results support the contention that low temperature strongly reduces growth rate but not growth efficiency of Antarctic protists, and highlight the need for caution when designing short-term experiments to measure ingestion rates of polar microzooplankton. MODELING THE MODIFICATION OF ORGANIC MATTER SINKING BY METAZOANS Metazoans have multiple impacts on the sinking flux of organic matter, through the packaging of fecal pellets, daily vertical migration, and long-term storage of nutrients. However, these ecosystem processes are difficult to discern on a global scale, given the scarcity of observations and the variability in the ocean environment. Here, we use the Biogeochemistry with Light Iron Nutrients and Gases (BLING) model to test the sensitivity of global biogeochemistry to specific metazoan activities. BLING is a structurally-efficient global model that uses a simple treatment of ecosystem structure to predict biomass and export, founded on the use of diagnostic tracers (i.e. tracers that are not subject to advection and diffusion, and do not conserve mass). We include organisms from different trophic levels in a computationally simple way by subdividing the prognostic organic matter tracer into organic matter components that evolve in time as diagnostic tracers. In this framework, we perform sensitivity tests to study how different parameterizations of particle modification influence the three-dimensional distribution of remineralization and export. (Abstract ID 12569)

Carranza, M. M., Scripps Institution of Oceanography, University of California San Diego, La Jolla, USA, maucarranza@ucsd.edu

LONG-TERM ACCUMULATION OF DOC IN THE UPPER LAYER AT BATS The Southern Ocean is the largest High Nitrate Low Chlorophyll (HNLC) region of the world’s oceans where primary productivity is primarily iron limited. Despite being an HNLC region, phytoplankton blooms occur annually and persist through the summer. A question that remains unanswered is what sustains blooms in the summer when presumably nutrients in the mixed layer have been depleted. The input of Fe to the euphotic zone depends in part on mixed-layer dynamics. The turbulent mixing caused by winds, along with the radiative forcing, prescribe the mixed layer depth (MLD). Changes in the MLD may facilitate the entrainment of Fe. In this work we explore the potential influence of nutrient entrainment on summer blooms by correlating CHL-a with physical variables such as SST and wind speed intensity (WSFP) using satellite estimates. We find SST fluctuations have the largest influence on CHL-a variability with statistically significant correlations over large areas in the Southern Ocean. The influence of WSFP on CHL-a variability shows more complex patterns. However, significant positive correlations suggest strong winds have a measurable influence in sustaining summer phytoplankton blooms. (Abstract ID 11883)

LEAD, CADMIUM AND COPPER CONCENTRATIONS AND LEAD ISOTOPIC DISTRIBUTION IN SEAWATER, SEDIMENTS AND CORAL IN THE NORTHERN PERSIAN (ARABIAN) GULF NEAR KUWAIT The objective of this study is to reconstruct chronologies of trace metals in the northern Arabian Gulf Kuwaiti marine environment, influenced by the Shatt al-Al Arab River’s load, using sediment cores and corals, and compare the historical variability to recent seawater data. Pb, Cd and Cu concentrations in seawater and sediments of the northern Persian (Arabian) Gulf were determined using isotope dilution (seawater and sediment Pb) and indium internal standard (sediment Cd and Cu) plasma mass spectrometry. Pb, Cd and Cu concentrations in seawater are high in the northern stations, including Kuwait Bay, Awhah and south of Buhayla Island. They show combined anthropogenic and riverine sources, while waters near two coral reefs by Kubar and Qaruh islands show high Pb, but low Cd and Cu. Surface sediment samples show metal enrichment in Kuwait Bay as expected for elements with anthropogenic enhancements. The 206/207Pb isotope data shows a large range, implying a variable mix of sources. The objective of this study is to reconstruct chronologies of trace metals in the northern Arabian Gulf Kuwaiti marine environment, influenced by the Shatt al-Al Arab River’s load, using sediment cores and corals, and compare the historical variability to recent seawater data. We demonstrate here that short-lived marine mollusk shells from Peru can be used as a quantitative paleoclimate archive for SST seasonal amplitude and ENSO variability in the tropical Pacific cold tongue. Because of low sea water δ18O variability on the Peruvian coast, quantitative paleoclimate archives for SST seasonal amplitude and ENSO variability in the SEASONALITY RECORDED BY SHORT-LIVED MARINE MOLLUSK SHELLS FROM PERU are quantitatively estimated by Monte Carlo simulations (MoCo program available at www.isem.cmu.edu/spip.php?rubrique472). \textit{Var(ΔT)} calculated from a shell sample yields a reliable estimate of the amplitude of ENSO variability. The uncertainty of these estimates, which depends on the sample size, stochastic noise, and biological limitations, can be quantitatively estimated by Monte Carlo simulations (MoCo program available at www.isem.cmu.edu/spip.php?rubrique472). This approach was applied to a modern reference for SST seasonality and ENSO activity. The SST seasonal amplitude \textit{(ΔT)} is strongly correlated to \textit{El Niño}+1 index. Therefore, \textit{Var(ΔT)} calculated from a shell sample yields relative measures of past changes in SST seasonality and ENSO activity, and are independent from the paleotemperature proxy model. We propose a comparison with coral records and model outputs based on ENSO anomaly frequency distributions. (Abstract ID 9869)

PLANKTONIC DIVERSITY IN LAGUNA GRANDE, PUERTO RICO

Laguna Grande is a 0.87 km² coastal lagoon located on the northeast coast of Puerto Rico. It is connected to Las Crobas Bay through a narrow 1.5 km-long channel. The lagoon and the channel are bordered almost entirely by Rhizophora mangle (Llaneza 1758). The water in Laguna Grande sustains high concentrations of the dinoflagellate 	extit{Pyrodinium bahamense} var. 	extit{bahamense} (Plate 1906), the organism responsible for most of the bioluminescence in the lagoon. Since 2004 we have been collecting water samples from Laguna Grande in order to study different aspects of the population ecology of dinoflagellates \textit{P. bahamense} var. 	extit{bahamense} and 	extit{Ceratium furca} (Ehrenberg 1834) Claparède & Lachmann 1869. High resolution images of planktonic organisms were taken during this research using Hamamatatsu Orca and Nikon DS series cameras, connected to a Nikon Eclipse E-600 microscope. Using these images we preliminarily identified organisms to the most specific taxonomic level that was feasible. We have identified at least 26 different taxa, including eight dinoflagellates, nine diatoms, two tintinnids, one vorticellid, one chaetognath, one medusae larvae, three arthropod larvae and one polychaete larva. READING BETWEEN THE LINES: BIVALVE GROWTH RATE AND ISOTOPIC VARIABILITY ACROSS THE BARENTS SEA POLAR FRONT

We examined shell growth patterns and tissue stable isotopic composition (δ13C, δ15N) of the Hairy cockle (\textit{Clistocardiun clathrum}) in the northwestern Barents Sea to evaluate the influence of different water masses and the polar front on growth rates and food supply over seasonal to decadal scales. Overall shell growth rates were highest in Atlantic water, intermediate in Arctic water, and lowest at the Polar Front. Temporal patterns of ontogenetically-adjusted growth (SGI) were correlated with regional climatic oscillation modes and local sea ice, with the highest growth associated with colder periods with more sea ice. Stable isotopic values of tissues progressively increased from Arctic to Atlantic waters, with the latter enriched in δ13C by up to 2.1% and δ15N by 1.5%. There were distinct seasonal and water mass variations in stable isotopic and C:N values, indicating both spatial and temporal variability in food supplies to the bivalves in this region. Integrating results of sclerochronological and stable isotopic analyses results provides additional insights on differences in food sources and pelagic-benthic coupling between water masses of the Barents Sea on small spatial scales. URBAN SOURCES AND REMOTE SINKS OF MARINE DEBRIS ON HAWAII ISLAND

Beach clean-up efforts by the Hawaii Wildlife Fund remove an average of 16 metric tons of plastic debris from the remote southeastern coastline of Hawaii Island annually since 2003. This coastline includes the infamous “Funk Beach” on Kamilo Point. Although much of the debris is fishing-based (such as nets), or of foreign origin (identified via foreign-language markings), some debris may have local sources. To identify the potential for locally-sourced debris, we installed floating boxes below storm water outfalls in Hilo, the island’s largest city, population ~40,000. The boxes trap floating litter washed down flood-control channels before it reaches the ocean. We quantified the amount and type of debris that was collected behind the boxes, and related the timing of debris movement to precipitation events. Releases of floating drifters offshore of Hilo and other population centers on the island mimicked the fate of Hawaii-sourced debris. Retention-boom monitoring and drifter recoveries are ongoing, but show how the build-up of debris at remote locations on Pacific islands is both an international and local problem. AN OMP-BASED APPROACH FOR DECONVOLVING SIMULTANEOUS TRENDS IN PROCESSES CONTROLLING SUBANTARCTIC MODE WATER PROPERTY DISTRIBUTIONS FROM HYDROGRAPHIC SECTIONS

Inferring long term trends in the processes that control mode water properties from pairs of hydrographic sections is complicated by shorter term variability resulting from frontal movements and transient eddies. Additionally, examining changes in the relationships between physical and biogeochemical properties (e.g. eMLR) in Subantarctic Mode Water (SAMW) is complicated by the influence of long term warming and freshening trends upon the physical properties themselves. Here we present an OMP-based inverse model that estimates changes in the relative influence of processes from differences in measurements of physical properties, nutrient concentrations, and carbonate system parameters, and that allows for the influences of vertical displacements of water masses. Application of this model to SAMW suggests long term warming and freshening trends in the intermediate and mode water masses forming in the Southeastern Pacific that are consistent with other published estimates obtained using data with higher temporal coverage. IMPACT OF OCEAN ACIDIFICATION ON ENERGETICS AND DEVELOPMENT OF PORCELAIN CRAB EARLY LIFE STAGES

Oceans are acidifying due to absorbing increased atmospheric CO2. Few studies assess impacts on coastal organisms and their early life stages. Porcelain crabs are common intertidal inhabitants with a complex life cycle. Little is known about the physiological mechanisms allowing larvae to transition from a stable CO2 environment (pelagic) to a habitat with CO2 fluctuations (intertidal). Are stages differentially affected by CO2? If so, which are most vulnerable? Embryos, larvae and juvenile 	extit{Porcellio petrobiolaris} were reared in ambient pH (8.0) and low pH (7.6). Metabolic rate, total protein, dry weight, lipid content and survival were determined at each stage. Results suggest significant maternal effects, however embryonic metabolism was 5% lower in individuals reared in low pH, while larval and juveniles displayed a trend of increased metabolic rate compared to control (7% and 39% higher, respectively). Alternatively, no differences were observed in larval dry weight or survival of larvae and juveniles. Certain stages may compensate for high CO2, however tolerance differs between clutches. Understanding responses to OA at different stages may indicate physiological mechanisms allowing organisms to persist in an acidifying ocean. (Abstract ID 12624)

UNCERTAINTY IN DETECTION OF HISTORICAL OCEAN CLIMATE VARIABILITY

This presentation explores the usefulness of past oceanic and atmospheric observing systems in detecting extreme tropical climate events through a set of observing system simulation experiments. In these experiments an initial simulation of the evolving ocean state during 1995-1998 is sub-sampled using the same distribution of surface and subsurface observations as exists in successive decades. The result is a set of synthetic ocean observation re-samples of the massive primarily tropical/subtropical climate anomalies of the 1995-1998 years. These synthetic observation re-samples are then assimilated into a general circulation ocean model using a conventional assimilation scheme. The results indicate that prior to the 1940s the historical observing network alone was only able to resolve limited aspects of ENSO. In contrast, by the 1960s the observing system was sufficient to resolve ENSO without additional wind information. When historical surface forcing is also included (with its estimated uncertainty) tropical ocean climate variability is reproducible even back to the early years of the 20th century. (Abstract ID 11575)

DUAL USE OF A SEDIMENT MIXING TANK FOR CALIBRATING ACOUSTIC BACKSCATTER AND DIRECT DOPPLER MEASUREMENT OF SETTLING VELOCITY

While the Acoustic Doppler Velocimeter (ADV) is designed to determine fluid velocity, it is important to recognize that it is actually the velocity of the scatterers themselves that is measured. Thus in a calibration tank designed to relate sediment-induced backscatter to sediment concentration, the vertical velocity registered by an ADV at a given point is actually the true fluid velocity plus the sediment’s settling velocity. And absent net vertical volume flux, the average vertical velocity registered by an ADV across a horizontal plane is equal to the mean sediment settling velocity. For this study, a series of ADV calibrations were run in a 118 liter re-circulating tank for six sand sizes between 63 and 150 microns. A grid of ADV measurements distributed in a horizontal plane across the tank revealed that the mean vertical velocity registered by the ADV in each case was indeed consistent with each grain size’s settling velocity as independently measured by a “rapid sand analyze” settling tube. In addition, a systematic increase in backscatter intensity for a given sand concentration was observed with increasing grain size. (Abstract ID 12707)

TRACKING THE EVOLUTION OF SUPER TYPHOON MEGI WITH SAR

Super Typhoon Megi developed on October 13, 2010 in the Western Pacific, crossed the Philippines on October 18 and made landfall in China on October 23. As part of the ONR sponsored Impacts of Typhoons on the Ocean in the Pacific program, twelve SAR images of Megi were acquired between October 14, 2010 in the Pacific and October 21, 2010 as the typhoon approached China. Six different satellites with X- and C-band radars were used to provide daily coverage and monitor the evolution of the typhoon. The 20 m to 150 m resolution imagery provides a unique ability to capture the small scale changes of the eye of the typhoon. Imagery shows a concentric eye wall structure develop on the approach to the Philippines. After the storm crossed the Philippines and entered the South China Sea, the eye became disfigured and disorganized. The SAR imagery shows the reorganization of the typhoon in the South China Sea as Migi intensified prior to making landfall in China. Comparisons with in situ measurements and model results will also be presented. (Abstract ID 12001)

PRESENCE AND FATE OF SR-90 IN SEAWATER OFF JAPAN AS A CONSEQUENCE OF THE FUKUSHIMA DAI-I-CHI NUCLEAR ACCIDENT

As a consequence of the Fukushima Dai-ichi nuclear accident, significant amounts of artificial radionuclides were released to the environment. The aim of this work, as part of a major collaborative effort, was to evaluate the presence and fate of 90Sr released to the marine system. Strontium-90 is a fission product originated in nuclear reactors that is present in the environment. A total of 58 samples from the surface waters and vertical profiles were collected and analyzed for 90Sr through the measurement of its decay product 90Y via radiochemical purification and beta counting. Preliminary results showed 90Sr concentrations enhanced by at least one order of magnitude at some stations. (Abstract ID 11054)

USE OF NITRATE AND NITRITE ISOTOPE TO STUDY NITROGEN CYCLING IN OCEANIC OXYGEN DEFICIENT ZONES

Oxygen deficient zones (ODZs) in the eastern tropical Pacific Ocean are important for marine nitrogen cycling and loss of fixed (bioavailable) nitrogen (N). Understanding the transformations of N in these regions requires a combination of approaches, including assessments of microbial distributions, activities, and stable isotope ratio measurements, which integrate over space and time. The measurement of nitrate and nitrite N and O isotopes provides insight into the coupled transformations of N in and around the ODZ. Here we present coupled nitrate and nitrite isotope data from the eastern tropical south Pacific Ocean from cruises in 2005 and 2010, which extended from coastal upwelling off of Peru into the subtropical south Pacific. They show increases in nitrate 815N and 818O values, and a corresponding increase in nitrite 815N, as nitrate concentrations decrease along isopycnal surfaces cutting through the ODZ. Above the ODZ, nitrate 815N values decrease again to values as low as -20‰. These patterns are indicative of recycling of N between nitrate and nitrite pools in and around the ODZ, as well as N2 production and loss from the system. (Abstract ID 9910)

THE AVHRR PATHFINDER SEA SURFACE TEMPERATURE CLIMATE DATA RECORD

Recently, the National Oceanographic Data Center (NODC) and the University of Miami released the latest version of the AVHRR Pathfinder Sea Surface Temperature (SST) climate data record (CDR) as part of the NOAA CDR program. This new Pathfinder Version 5.2 (PFV5.2) data set spans 1981-2010 and represents a significant step forward in the maturity of the SST CDR. Compliant with the Group for High Resolution SST (GHRSST) Data Specification version 2.0 (GDS2), produced using the freely-available SeaDAS software environment, and accepted as the first ocean CDR by the NOAA CDR Program, the PFV5.2 data are more complete, understandable, and accessible than any previous version. Full documentation, software, and ancillary data are available to ensure reproducibility of the CDR. Evaluations of the new PFV5.2 data set will be presented, highlighting strengths and the new capabilities now possible through its GDS2 compliance. These new capabilities include being able to examine sea ice fraction, aerosol loading, and wind speed information on the same time-space grid. The evaluations will also highlight shortcomings that are being addressed in the future Pathfinder Version 6. This 6th generation of Pathfinder is currently under development and its progress in reducing seasonal and latitudinal varying biases present in PFV5.2 will be reviewed along with descriptions of the techniques to be used in generating the GHRSST-mandated uncertainty estimates for each SST observation. FEEDING ECOLOGY AND METABOLISM OF EUCALANUS INERMINIS IN THE EASTERN TROPICAL PACIFIC OCEAN: IMPLICATIONS FOR VERTICAL CARBON TRANSPORT

The eastern tropical Pacific Ocean contains one of the most severe oxygen minimum zones (OMZs). *Eucalanus inermis* is an abundant copepod species in this region, and shows a bimodal vertical distribution with major abundance peaks in the upper OMZ and near the chlorophyll maximum. Our study examined feeding preferences and metabolic rates of individuals residing at the two depths. Lipid analyses of copepods and potential food suggested that *E. inermis* adult females fed primarily near the chlorophyll maximum. Results from metabolic experiments indicated that shallow-dwelling *E. inermis* utilized primarily proteins for catabolism, while individuals collected from depth learned more towards lipid catabolism. Additionally, OMZ conditions of lower temperature and oxygen led to increased percentages of nitrogen excretion in the form of urea. This presents a scenario in which *E. inermis* provides net carbon transport from the shallow depths to the upper OMZ, although the amount and type of carbon which is remineralized at each depth via metabolism is likely different between the two groups. SWASH-CUSP INTERACTIONS ON A REFLECTIVE BEACH

Steep beaches commonly adopt a cuspate form, the result of swash-topography interactions associated with the feedback between cusps and swash. These interactions, in turn, affect local swash-swash interactions in a longshore variable way. The final result is a time-varying cusp response that includes growth, decay and varying length scales, none of which is currently predictable. The goal of the present workshop is to understand these swash interactions and their interplay over a well-developed cuspathe beach. In June, 2010, five Argus cameras were installed at Massaguacu Beach, Brazil. This foreshore is steep, commonly cuspy and highly variable over short time scales. To approximate topography at any time, a generic cusp terrain model was used to simulate the evolution of the swash zone. This foreshore is steep, commonly cuspy and highly variable over short time scales. To approximate topography at any time, a generic cusp terrain model was used to simulate the evolution of the swash zone. This foreshore is steep, commonly cuspy and highly variable over short time scales.
Variability in wind stress curl and sea surface temperature (SST) fronts near Cape Frio (42°W, 22°S) is tightly coupled. Multi-year SST observations obtained from the Group for High Resolution Sea Surface Temperature (GHRSSST) and winds from QuikSCAT are combined with numerical modeling simulations to quantify how much of the temperature variability is driven by the wind stress curl, and how much of the wind stress curl variability is driven by SST fronts via air sea interactions. Analyses show that both the temporal and the spatial variability in wind stress curl are highly correlated with variability in SST gradients, suggesting that a significant fraction of the wind stress curl variability is associated with air sea interactions. Once in wind stress curl are highly correlated with variability in SST gradients, suggesting that a significant fraction of the wind stress curl variability is associated with air sea interactions. Once in wind stress curl are highly correlated with variability in SST gradients, suggesting that a significant fraction of the wind stress curl variability is associated with air sea interactions.
The formation, destruction, and transport of SAMW are examined using a eddy-permitting ocean circulation model constrained to a large observational dataset - the Southern Ocean State Estimate. Both a freshwater flux (net precipitation causing freshening) and an air-sea heat flux (which can be of either sign) significantly contribute to buoyancy fluxes in the SAMW density range complicating estimates of formation rates. Transformation occurs both at the surface due to air-sea buoyancy fluxes, and in the interior due to mixing; the relative roles of these two processes varies across different ocean sectors. For the years 2005 and 2006, SAMW (26.7°C, sigma theta = 27.0) was predominantly formed in the Indian Ocean both by the air-sea buoyancy fluxes and by interior mixing. In the Atlantic sector of the Southern Ocean the same mechanism was used to destroy interior mixing, while it was transported southward in the Pacific. The formation of SAMW in the Southern Ocean surface formation of SAMW was insignificant and SAMW was destroyed by interior mixing. SAMW is transported northward in all three ocean sectors. As part of a coordinated observational and modeling program sponsored by ONR to study submesoscale lateral mixing, multiple releases of fluorescein dye were injected at 35 m depth during June 2011 and tracked using a towed Moving Vessel Profiler system. Two different sites in the Sargasso Sea were selected for these dye releases: a region with low horizontal strain near the center of a cyclonic eddy; and near a density front with strong velocity gradients. In order to observe the evolution of the dye as accurately as possible, considerable effort was focused on determining the response function of the temperature, conductivity and fluorescence sensors. We investigate the diapycnal diffusion of the fluorescein patch in the two study sites by examining the dye distribution in density space. The characteristics of the diffusion in both the high and low shear/strain regions are discussed. (Abstract ID 11627)

RELATIONSHIPS BETWEEN THE PARTICULATE ORGANIC CARBON, PLANKTON COMPOSITION AND OPTICAL PROPERTIES DURING NORTH ATLANTIC BLOOM 2008

The co-variability of optical scattering and particulate organic carbon (POC) provides a basis for estimating POC from ocean color satellite and in-situ measurements by autonomous platforms on larger spatial and temporal scales that surpass traditional (and limited) discrete water sampling and chemical analysis. These proxies when applied globally, however, overlook the inherent dependence of POC-optical relationship on plankton community and particulate composition. During the North Atlantic Bloom experiment of 2008 (NAB08), we accrued a large dataset consisting of >300 POC samples and simultaneous chlorophyll fluorescence (ChlF), particulate attenuation (c_p) and particulate backscattering (b_p). An optical ‘community index’ (ChlF/c_p) differed between plankton community types, reflecting changes in community composition and phytoplankton physiological status. A shift in surface plankton community composition was reflected in POC/c_p, but not in POC/b_p. Both POC/ c_p and c_p decreased with depth as a function of changing particle composition and organic content. Results of a detailed analysis of previously published POC optical proxies indicate that knowledge of both community and particulate composition is needed for successful application of carbon proxies in the ocean. NORTH ATLANTIC BLOOM 2008 WEBINAR SERIES

The 2008 North Atlantic Bloom Experiment (NAB08) was a collaborative effort to observe an entire phytoplankton spring bloom and included the use of heavily-instrumented autonomous platforms that sampled biogeochemical parameters relevant to aspects of the bloom. To broadly disseminate results and contribute to the public’s understanding of ocean science, NAB08 participants collaborated with the Center for Ocean Sciences Education Excellence (COSEE) - Ocean Systems to present a series of five webinars describing the motivations and findings of this multidisciplinary experiment. Weekly webinars targeted a wide community of educators, scientists, and students and used interactive concept maps enriched with educational assets to deconstruct and present complex ocean science content. The series allowed geographically separated NAB08 scientists to reach participants from 21 different U.S. states and several countries. Guided-inquiry datasets, utilizing NAB08 data, were developed, presented and made available to download at each webinar. Post-webinar evaluation showed that 31% of the audience was comprised of researchers and 51% of educators. A high audience retention rate demonstrated the effectiveness of a coordinated series of webinars on a complex scientific endeavor. (Abstract ID 9966)

CONNECTING OCEAN SCIENTISTS WITH FUTURE EDUCATORS - COSEE FLORIDAS RESEARCH EXPERIENCE FOR PRE-SERVICE TEACHERS

To bring real world ocean science into the classroom, COSEE Florida’s Research Experience for Pre-Service Teachers (REPT) program provides an opportunity for future science teachers to work with marine scientists on research projects. In 2011, six middle school education majors at Indian River State College in Fort Pierce, FL, participated in a seven week summer experience. Scientist teams at Harbor Branch Oceanographic Institute, Smithsonian Marine Station, and Ocean Research & Conservation Association each mentored two students for 20 hours of research per week with 5 hours of support from IBSC faculty. Mentors helped students develop a scientific poster describing their research and guided them in the production of a video vignette addressing a misconception about the nature of science. The program provided future teachers with an authentic and deeper understanding of scientific practices and gave ocean scientists a meaningful opportunity to contribute to ocean science education. In future years, COSEE Florida will focus on enhancing mentoring skills and work to adapt the model for use by scientists in other academic or research settings as a broader impacts activity. THE DISTRIBUTION OF MANGANESE IN THE SOUTHWESTERN EAST/JAPAN SEA

The distribution of total dissolved Mn was determined in the southwestern East/Japan Sea three times on April 2006, May 2007 and August 2007. Water samples were taken at recommended standard water sampling depths. Sampling sites covered water depths from 516 to 2308 m. The concentrations of manganese changed greatly by sites from 2.0 to 1.49 nM in surface waters. The vertical profiles of manganese show high concentrations at the sea surface and rapid decrease to mid-depths (800-1000m). Below 1000m water depths, the manganese concentrations increased rapidly downward the water column at most sites of the study area. The manganese concentrations vary with depth from 0.9-380 nM. The surface high and downward decreasing trend in the manganese concentrations is interpreted such that manganese is desorbed from the atmospherically driven particles at the surface waters and then scavenged by particles on the way to deposition to the seafloor. The downward increasing manganese concentrations below 1000m water depths, which is occurring over the whole study area, indicate that there may be significant benthic fluxes of dissolved manganese from sediment. The findings suggest benthic fluxes together with atmospheric input of manganese may contribute greatly to the mass balance of manganese in the East/Japan Sea. (Abstract ID 10594)
The Northern Gulf of Mexico (NGOM) is a complex but poorly quantified coastal ocean margin, and its contribution to the North American carbon budget is not well known. The strength of the biological carbon pump and, specifically, the balance between autotrophic (photosynthesis) and heterotrophic (respiration) processes are important in influencing carbon dynamics in the NGOM. A key to understanding variations in the strength of the biological pump is information about phytoplankton community structure and light absorbing properties. The coastal margins of NGOM were extensively sampled as a part of the GulfCarbon program and associated projects funded through NSF, NASA and NOAA, with the goal of characterizing the taxonomic composition, size indices, biomass and associated bio-optical properties of the phytoplankton community. Results showed distinct spatial and temporal patterns in the observed variables. Key environmental drivers appear to be seasonal variations in freshwater discharge and nutrient dynamics. Results also suggested the importance of vertical mixing, wind and current dynamics within the region. These findings should help to refine regional carbon fluxes and thus modeling efforts in estimating the North American carbon budget. (Abstract ID 10749)

PHYTOPLANKTON COMMUNITY DISTRIBUTION AND LIGHT ABSORPTION PROPERTIES IN THE NORTHERN GULF OF MEXICO

Regions of permanent water column suboxia or anoxia are well-recognized centers of fixed nitrogen loss. Along the California Current, coastal upwelling drives the seasonal formation of hypoxia over the continental shelf but only occasionally are suboxic/anoxic conditions observed. Using data spanning a decade of observations from the Oregon coast, we find evidence of substantial fixed N-loss (from N\textsubscript{2}) that vary in concert with temporal changes in water column oxygen. Constraints based on DICR, AOU, stoichiometries and N2Ar suggest that N\textsubscript{2} anomalies serve as a coherent proxy for N-loss in the system. Observations of strong negative N\textsubscript{2} anomalies despite the absence of water column suboxia point to a dominant role for sedimentary N-loss. Slope–shelf contrasts further indicate that N-losses are not due to advection but are generated locally over the mid-shelf. We further evaluate observed N-loss in relation to modeled sedimentary N-loss under expected and enhanced sensitivity to water advection but are generated locally over the mid-shelf. We further evaluate observed N-loss for sedimentary N-loss. Slope–shelf contrasts further indicate that N-losses are not due to negative N\textsubscript{*} anomalies despite the absence of water column suboxia point to a dominant role that N\textsubscript{*} anomalies serve as a coherent proxy for N-loss in the system. Observations of strong evidence of substantial fixed N-loss (from N\textsubscript{*}) that vary in concert with temporal changes in water column oxygen. Our results support the idea that the enhancement of water column hypoxia can greatly accentuate the magnitude of sedimentary N-losses from productive, carbon-rich upwelling shelves. EFFECTS OF OCEAN ACIDIFICATION ON PHYSIOLOGICAL AND SWIMMING PERFORMANCE OF LARVAL ECHINOIDS

Planktonic larvae of many marine invertebrates, particularly those in extratropical and upwelling areas, often experience pH fluctuations and therefore may be pre-adapted to ocean acidification (OA). Previous OA studies have focused on larval mortality, with less emphasis on sublethal effects. Observed sublethal effects could nonetheless have significant population-level impacts by affecting larval dispersal and survival. We compared OA sensitivity in four different echinoids ([A]mphiura \textit{filarina}[s], \textit{B}rissopsis \textit{hydria}, \textit{D}endraster excentric\textit{us}, \textit{S}trongylocentrotus \textit{purpuratus}) differing in habitats and/or ambient pH during their spawning season. We monitored OA impacts on physiologies (growth, feeding and respiration) and quantified swimming behaviors using non-invasive video tracking. Because environmental variables (prey and predator abundance, advective currents) usually vary with depth, vertical swimming strongly affects larval dispersal and survival. Our results suggest that OA delayed larval growth across species, but that OA-induced morphological and behavioral changes varied between species. For at least one echinoid, \textit{D. excentric\textit{us}}, OA-induced morphological changes appeared to impact feeding but not swimming, implying a functional trade-off. Species-specific abilities to cope with future ocean conditions. (Abstract ID 12562)

SCIENTIFIC PROCESS IN PRACTICE, AN ACTIVITY BASED SEMINAR FOR BEGINNING OCEANOGRAPHY MAJORS

"Scientific process in practice" was a 2 hour long, weekly, activity based seminar designed to explicitly teach scientific process skills. This seminar complemented an existing, mandatory field course for entering oceanography majors. The goal of the seminar was to help students succeed in the field course and future science courses by 1) developing information literacy skills; 2) practicing articulation of testable hypotheses; and 3) studying the form of scientific presentation. We assessed the effectiveness of the seminar qualitatively and quantitatively. Over 90% of the students' stated in their course evaluations that class sessions were always interesting and engaging. Examples of activities included citation format detective, figure critique speed dating, and statistics learning carousel. Pre- and post-course surveys showed that the seminar improved students self-efficacy towards conducting scientific research. Relative to students enrolled in the field course alone, students in the complementary seminar showed greater gains in the Student Understanding of Scientific Inquiry Survey. Our results suggest that an explicit, inquiry-based courses focusing on transferrable skills can help improve students' learning experience and understanding of science. (Abstract ID 12572)

PROJECTED MIXED LAYER DEPTH CHANGE IN THE NORTH PACIFIC OCEAN AND ITS IMPACT ON PRIMARY PRODUCTION

This study examines changes in the mixed layer depth (MLD) in the North Pacific Ocean (NP) in response to global warming and their impacts on primary production by comparing outputs from eleven models of the coupled model intercomparison projects phase 3 (CMIP3). We find consistent MLD changes in future in the NP from most of the eleven CMIP3 models: a shoaling in the KE region and a deepening north of the Kuroshio front. The shoaling is attributable to the weakening in the windstress and the associated decrease in the ocean cooling in the KE, whereas the deepening is mainly driven by the northeasterly wind in the KE. In the 21st century, the entrainment production, estimated by MLD changes, in the KE will decrease by 107–403% and spring blooms will occur 0–13 earlier in response to the changes in MLD in the KE region. Despite the consistent changes, the magnitude of changes in primary production and the timing of the spring blooms are quite different depending on models and latitudes. (Abstract ID 10202)

MICROZOOPLANKTON GRAZING IMPACT IN THE EAST CHINA SEA
The size dependent phytoplankton growth and mortality rate, according to Metabolic Theory in Ecology, together shape its size structure, which would critically regulate the nutrient and energy transfer efficiency. This study aims to identify the detailed size specific growth and mortality of microphytoplankton, on which studies are scarce. We first hypothesize that the size-specific growth rate and mortality scales with the body size with an exponent of -1/4 after temperature correction in natural microphytoplankton assemblage. We simultaneously measure the high resolution size specific growth and mortality rate of microzooplankton by incorporating the FlowCAM into dilution technique, which were conducted in the East China Sea from 2010 to 2011. Our results first illustrate that, under log scale, the mass-specific growth rates positively scales with body mass, while the mortality rates show insignificant relationship with body size. We further suggest that grazing impact also exhibit non-significant regression with body size. The well coupled size-specific growth and mortality rates, on the other hand, implies that the microzooplankton community would selectively feed on those fast growers. This detailed information would shine light on the dynamic of microphytoplankton size structure. Keywords: Dilution experiment, Microzooplankton grazing, East China Sea, Size specific growth rate, Size specific mortality rate (Abstract ID 9595)

KUROSHIO-INDUCED WAVE IN THE LEE OF GREEN ISLAND
The Kuroshio's pathway runs parallel to Taiwan's eastern coastline with a width of ~100 km and a current speed of 1-1.5 m/s-1. The wave induced by current-island interaction could significantly change the current's flow patterns and properties. In this study, vertical profiles of shipboard Lowered-ADCP and CTD reveal large differences in flow characteristics upstream and leeward of Green Island, located southeast of Taiwan in the main Kuroshio axis. Two stages of wave evolution were observed respectively from two separated legs of shipboard measurement. In the first stage, a trapped eddy emerges to the leeward side of island, followed by a tail with Vortex Street-like structure. In the second stage, the trapped eddy sheds from the leeward side to ~6 km downstream north of the island and a rudimentary eddy appears at the island's leeward side. The wave water is colder, saltier, and has a higher chlorophyll a, and produces ~50 % more diatoms compared to the open ocean, suggesting that the vertical shear drives the turbulent mixing and thus produce the cold and salty dome in the wake. (Abstract ID 10104)

WHY DOES THE LOOP CURRENT HAVE SEASONAL PREFERENCES FOR SHEDDING EDDIES?
The Loop Current is the major source of the Gulf Stream; it carries waters that make up almost all of the upper limb of the meridional overturning circulation of the tropical and subtropical North Atlantic Ocean, and thus can have significant impact on the global climate. In particular, the heat and salt) that the Loop Current carries play an important role in regulating the weather and climate of the continental US. The Loop Current is well-known for its highly nonlinear and apparently erratic behavior of shedding warm eddies, yet since the early 60's some oceanographers suspected some seasonal preferences for eddy-shedding. I will explain why this must be so using observational data as well as analytical and numerical model analyses. (Abstract ID 9629)

OCEANIC THERMAL VARIATIONS UNDER TYPHOOON LUPEIT (2009)
Three surface buoys equipped with surface meteorological sensors and subsurface temperature sensors were deployed in the northwestern Pacific. Typhoon Lupit (2009), a category-5 typhoon in Saffir-Simpson hurricane scale, passed over one buoy with its eye and another buoy with its eye wall when it weakened from category 3 to 2. All buoys worked well except with a few instrument failures after Lupit passage. Highest wind speed of 60 m/s and lowest
air pressure of 941 mb were recorded under the eye. Sea surface temperature (SST) dropped by 3.5 °C under the eye and 4.5 °C under the eye wall. Meanwhile, temperature in the upper thermocline increased first before decreasing, indicating the domination of vertical mixing in the forced stage. Upper ocean heat content in the top 100 m showed post-tropical near-inertial oscillation for 5 days and did not bounce back thereafter. In addition to the seasonal cooling, satellite-observed sea surface height anomaly suggested that a cold eddy was also responsible for the long-lasting cooling. (Abstract ID 10831)

AN ASSESSMENT OF OCEANIC VARIABILITY FOR 1960-2010 FROM THE GFDL ENSEMBLE COUPLED DATA ASSIMILATION

The Geophysical Fluid Dynamics Laboratory (GFDL) has developed an Ensemble Coupled Data Assimilation (ECDA) system based on the fully coupled climate model, CM2.1, in order to obtain accurate oceanic initial conditions that are balanced with the climate prediction model. This study provides a comprehensive evaluation for the oceanic variability from the latest version of the ECDA analyzed for 51 years, 1960-2010. Meridional oceanic heat transport, net ocean surface heat flux, wind stress, sea surface height, top 300m heat content (HC300), tropical temperature, salinity and currents are compared with various in situ observations and reanalyses. Results show that the ECDA agrees well with observations in both climatology and variability for 51 years. While systematic model errors are mostly corrected with the coupled data assimilation, some model biases have not been completed eliminated. In terms of the climate variability, the ECDA provides good simulations of the dominant oceanic signals associated with ENSO, IOD, PDO, and AMOC during the whole analyzed period, 1960-2010. DYNAMICS OF LATERAL CIRCULATION IN A COASTAL PLAIN ESTUARY.

A dense 10-element mooring array was deployed in the James River Estuary to quantify the structure of lateral, along-channel and vertical flows in order to quantify the role of lateral advection in rectifying estuarine exchange flow. During the deployment, stratification varied by a factor of 5 over the spring/neap cycle, with near-tides characterized by enhanced exchange flow and modestly reduced lateral flows. Lateral flows were highly coherent across the array with their structure, magnitude and dynamical balance consistent with the superposition of Ekman processes and differential advection. Lateral flows tended to be stronger than a simple Ekman scaling on flood tide and slightly weaker on ebb. The mooring array was sufficiently dense to infer tidal period vertical motion that, together with the lateral circulation, revealed laterally asymmetric closed secondary circulation cells with peak vertical velocities of 0.5 mm/s. These 3-D velocity fields will be used to estimate advective accelerations and determine their influence on tidal and subtidal dynamics. In addition, results will be placed in context with estimates of mixing determined from concurrent dye experiments and microstructure data. (Abstract ID 12049)

BLENDING SEA SURFACE SALINITY DATA FROM IN SITU PLATFORMS AND MULTIPLE SATELLITES

On the weekly basis, there are several thousands sea surface salinity (SSS) measurements from in situ platforms (e.g., satellite drifting buoys, moorings, ships, and profiling floats). Today, there are two remote sensing satellites (SMOS, Aquarius/SAC-D) that measure the ocean brightness temperature that can be used to retrieve SSS. To blend these SSS data with apparently different spatial and temporal resolutions as well as error statistics, we are proposing a two-dimensional variational (MS-2DVAR) blending algorithm, which is successfully used to blend the sea surface temperature (SST) data from in situ platforms and multiple satellites (http://sst.jpl.nasa.gov). The 2DVAR method considers inhomogeneous and anisotropic background error covariance specifically developed to emphasize regional characteristics in SST and SSS. We will present the results of using the 2DVAR to blend SSS data from in situ platforms and multiple satellites. (Abstract ID 10828)

RAPID VARIABILITY OF OCEANIC JETS DRIVEN BY EDDY-TOPOGRAPHY INTERACTION

Recent observations of the Southern Ocean from fixed moorings and satellite altimetry have revealed that the jets (or "fronts") that make up the Antarctic Circumpolar Current show peculiar variability in the vicinity of large, sub-surface topographic features. Two (or more) jets that pass near the same topographic feature display anti-correlated behaviour, where one jet will increase in strength at the expense of others. This variability can manifest itself in dramatic ways, with a particular jet changing its "preference" for a topographic feature. For example, a jet that previously skirted a plateau to the north, can very rapidly shift to skirt the plateau to the south. Shifts in the latitudinal position of jets of more than 10 degrees have been observed. We will present a theory explaining the variability of surface currents, built on the results of an idealised numerical model. We posit that it is the interaction of turbulent eddies and topographically driven flow in the abyssal layers that explains the observed variation in surface mean currents. The feedback of mean flow onto the eddies will also be discussed. (Abstract ID 10650)

A NEAR FUNDAMENTAL DEcadal DATA RECORD OF AIRs infrared BRIGHTNESS TEMPERATUREs

Aqua provides a direct measurement of the surface infrared radiation for nine years from a single satellite platform with two completely independent instruments (AIRS and MODIS). We produced a 0.5x1.0 deg, lat-lon daily gridded potential fundamental decadal data record (FDDR) of AIRS surface brightness temperatures (BT) in the 4u and 12u windows. We show on a decadal time scale correlations of surface BT with GISS global surface temperatures are 0.79 and 0.85, respectively. The FDDR global annual surface BT warming trend is 0.15°C per decade in the 3.8u. The warming trend is 0.17°C and 0.03°C per decade, respectively in the Polar Regions. The southern Polar Region trend is twice the northern trend. By convolving AIRS with the MODIS SRF, a seasonal comparison with MODIS shows a difference of 0.05°C. We are also verifying the instruments have not degraded by comparing AIRS convolved and MODIS for the same day in September for each of 10 years. We conjecture that direct satellite level IR radiance sounding observations will yield the first FDDR. (Abstract ID 10607)

THE IMPACT OF AN INVASIVE BIVALVE ON TWO SYSTEMS WITH DIFFERENT NUTRIMENT CONCENTRATIONS

Invasive bivalve species have proved to be problematic worldwide as they cause changes in both benthic and pelagic zones, linking these two normally distinct areas. One such bivalve is Corbicula fluminea, a clam species that has spread internationally due to humans. Mesocosm studies were conducted to determine the impact of C. fluminea on the phytoplankton community and nutrient concentration. Two different lake systems were replicated: one mesotrophic, one eutrophic. Four treatments were used in order to determine whether the impact of C. fluminea varies with sediment presence or absence. The initial nutrient level does not seem to influence the impacts of C. fluminea as similar fluctuations in phytoplankton biomass and nutrient concentrations were observed in both experiments. Nutrient concentrations, specifically nitrate and phosphate, were affected more by the presence of sediment than the presence of C. fluminea. The clams seem to prevent pennate diatoms from dominating the phytoplankton community. This study depicts the impact an invasive bivalve introduced through anthropogenic activities can have on differing environments. (Abstract ID 12191)

MONITORING IN SITU Tidal SCALE AND SURFACE AQUFER RECHARGE AND DISCHARGE ON WALLOPS ISLAND, VIRGINIA

Wallops Island, a barrier island on Virginia's eastern shore, is home to NASA's Wallops Flight Facility. The island often experiences major erosion, flooding, and overwash in times of elevated sea-level, however little is known about local tide and wave height conditions along the shoreline. We collected baseline tidal and aquifer data between April -October 2011 using SOLINST dataloggers. In-situ tidal range and tide cycle data allows us to investigate the impact
of tides on aquifer discharge and recharge rates. There is an observable signal in the aquifer that correlates to daily tide data from nearby Curtis Merritt Harbor. These data also show that the surface aquifer recharges approximately 45 minutes after rainfall events. Beginning in November 2011, NASA plans to replenish the beach in order to minimize damage to existing infrastructure. In order to support NASAs effort to develop a shoreline management plan, we will continue data collection through 2012 and compare conditions pre and post-replenishment to determine what impacts, if any, beach replenishment has on the natural barrier island system. NITROGEN-LOSS PATHWAYS IN THE SAN PEDRO AND SANTA MONICA BASINS DETECTED FROM N2/AR RATIOS AND NITRATE ISOTOPES

Nitrogen cycling dynamics were investigated in the Santa Monica (SMB) and nearby San Pedro Basin (SPB) in 2011. The relationship between the excess N2 (determined from high-precision N2/Ar ratios) and corresponding nitrate deficit was assessed in this system where sedimentary N loss processes are expected to dominate. During summer in the SPB, excess N2 reached a maximum of 28μM of N in the oxygen deficient waters below the sill depth, which agreed well with N loss expected according to the nitrate deficit. In contrast, excess N2 in the SMB during winter 2011 was 18 to 63% greater than that expected from the nitrate deficit. In both basins no enrichment in 15N and 18O-nitrate was observed, which is expected when dissimilatory nitrate reduction occurs in the water column, hence supporting the theory that N loss in this system occurs solely in the sediment. The spatial and temporal variability of excess N2 will be discussed along with potential processes leading to the deviation observed between excess N2 and the nitrate deficit in the SMB and potential implications for the global N budget. OBTAINING QUALITY AC-S METER SPECTRA: A METHOD FOR TEMPERATURE AND RESIDUAL SCATTERING CORRECTIONS

The ac-spectra (ac-s) in situ spectrophotometer (WET Labs) measures the absorption a(λ) and beam attenuation c(λ) spectra of water samples, either in the laboratory or the field. The high spectral resolution (1 nm) of the instrument allows for precise temperature and scattering corrections to be applied during data processing. Here we present ac-s data collected in the Gulf of Maine as part of the 2011 Ocean Optics Summer Course. We show a technique for deriving accurate water temperature from the residual correction of the a(λ) and c(λ) data, and explore a method for diagnosing errors induced by variable flow-rate of the instrument package. We also examine a method to correct for residual scattering in the a(λ) data and simultaneously separate a(λ) into a(λ) and a(λ) components. All of these steps, displayed here in a schematic diagram, are critical for accurate calibration-independent in-situ corrections of ac-s data. Determining appropriate processing and correction methods for ac-s data is essential for the field of optical oceanography, as hyperspectral measurements are increasingly used to both diagnose in-situ properties and relate them to remotely sensed quantities. IMPACT OF RESOLUTION ON THE GULF STREAM SEPARATION AND PATHWAY

The accurate representation of western boundary currents’ separation and pathways in eddy-resolving numerical models remains a challenge. The Gulf Stream separation and pathway

are investigated in a series of nested configurations of increasing horizontal resolution (1/12°, 1/29°, 1/50° and 1/100°) using the Hybrid Coordinate Ocean Model (HYCOM). The regional configuration is centered over Cape Hatteras and is nested within a global 1/12° HYCOM simulation. Each sensitivity experiment is integrated for 5 years, starts from the same ocean state, and is forced with the 0.5° NOLAPS atmospheric fields used in the global simulation. In addition to the impact of the horizontal resolution, we will also report on the sensitivity of the solution to a) boundary condition formulation and strength, b) representation of the Deep Western Boundary Current, c) bottom topography, and c) the surface forcing. Energy and vorticity budgets are used to analyze the simulations and quantify the differences. (Abstract ID 11658)

UNCERTAINTIES IN AIR-SEA BOUNDARY FORCING AND IMPLICATIONS FOR OCEAN MODELING AND STATE ESTIMATION

We investigate the uncertainties related to atmospheric fields from reanalysis products used in forcing ocean models. Reanalysis products from (1) European Centre for Medium Weather Forecasts (ERA-Interim), (2) Common Reference Ocean–Ice Experiments (CORE-2), (3) Japanese Reanalysis Project (JRA-25) and (4) National Centers for Environmental Prediction/ National Center for Atmospheric Research (NCEP/NCAR) are evaluated globally against satellite-derived observations for eight different fields (zonal and meridional wind stress, precipitation, specific humidity, river runoff, surface air temperature, downwelling longwave and shortwave radiation fluxes). No single product is found to agree better in all fields with satellite-derived observations. Time-mean and time-variable errors are estimated separately and mapped globally in space, based on 14-day average fields to focus on interannual periods. Precipitation and wind stress show largest uncertainties amongst all the fields. Furthermore, we use each set of atmospheric fields to force the same MITgcm ocean model setup from 2000-2005. Respective solutions are compared to determine different uncertainties in the ocean state due to uncertainties in atmospheric forcing. The spatial (vertical, horizontal) and temporal extent of ocean state errors are presented. (Abstract ID 11357)

BIO-OPTICAL PROPERTIES AND IN-WATER CONSTITUENT RELATIONSHIPS IN THE CHUKCHI AND BEAUFORT REGIONS OF THE ARCTIC OCEAN

During the two-year ICESCAPE campaign to the Chukchi and Beaufort regions of the Arctic Ocean we performed coincident, near surface water column measurements of apparent and inherent optical properties, phytoplankton pigments, CDOM and particle absorption, and dissolved and particulate organic carbon, at 34 stations. We analyzed the absorption and scattering components of calculated remote sensing reflectances in the context of the measured dissolved and particle loads, in order to improve our understanding of the uncertainty sources for bio-optical parameters in this high-latitude environment. Relatively higher CDOM and detrital absorption components, as well as sharp near-surface vertical stratification, influence the accurate retrieval of phytoplankton pigments and other biogeochemical constituents with standard remote sensing algorithms. Our results have implications for the calibration and validation of current and future ocean color mission through improved algorithm development. (Abstract ID 12065)

MARINE PHOTOSYNTHETIC PLANKTON DYNAMICS: WHERE ARE WE AFTER 50 YEARS?

Over the past decades new information from emerging technologies has added to early conceptual models of marine photosynthetic plankton abundance and distribution. The important marine photosynthetic planktonic groups have been revised and what regulates their growth and abundance better defined. Still many questions remain. Why and when do certain groups bloom/dominante? How do they spread and where do they hide? What keeps others...
from proliferating? This type of information is important for a variety of reasons including: 1) determining the health of the oceans; 2) predicting how ocean ecosystems will change in the future; 3) understanding evolution and growth of harmful algal blooms. This presentation first reviews early conceptual models regarding what determines the different life forms of marine photosynthetic plankton. It then highlights the results from interdisciplinary studies and time series studies and how these have changed the early views. We conclude by speculating about the present state-of-the-art and what might be the next steps for the field. (Abstract ID 10419)

LASER FLUORESCENCE PHYTOPLANKTON ANALYSIS ACROSS A FRONTAL ZONE IN THE CALIFORNIA CURRENT ECOSYSTEM

Spatial variability of chlorophyll, phycoerythrin, chromophoric dissolved organic matter, and variable fluorescence, Fv/Fm, were analyzed using Advanced Laser Fluorometer (ALF) to assess chlorophyll concentration (Chl), autotrophic and Synechococcus carbon biomass (AC and SYN). Three distinct autotrophic assemblages were identified. The fluorescence retrievals were 3-4 times higher in cooler mesotrophic waters north of the front than in warm oligotrophic waters to the south. Northern waters were also distinguished by a subsurface pigment maximum of blue-water type of Synechococcus and by the presence of green-water Synechococcus and cryptophytes. The highest Chl and AC values were found in a 20-40 m diatom-dominated maximum at the front, accompanied by elevated Fv/Fm and minimal SYN. The underway ALF sampling detected an abrupt transition from low to high SYN occurred at the front on the northern side of a sharp salinity gradient. Strong regression relationships were found for chlorophyll fluorescence vs. Chl (R2=0.95) and AC (R2=0.79). Synechococcus-specific phycoerythrin fluorescence (FPE12) and SYN also highly correlated in surface waters (R2=0.95). Increased chlorophyll fluorescence yield in the diatom-dominated front waters and increase in FPE12/SYN with depth were observed. (Abstract ID 11920)

PHYTOPLANKTON FLUORESCENCE FILLING THE GAP BETWEEN OBSERVATIONS AND UNDERSTANDING

Measuring in vivo fluorescence from phytoplankton photosynthetic pigments provides information about their biomass, physiology, photosynthetic rates, and community structure. Such measurements are sensitive, non-intrusive, rapid, and easy to conduct. However, the interpretation of fluorescence data remains challenging: applying insights gained in the laboratory to measurements taken in natural aquatic environments is difficult, and understanding the sources of variability observed in the field is complex. Nevertheless, from satellites to flow cytometers, from emission-excitation spectra to time-resolved measurements, a broad array of tools and protocols have been developed and utilized to address specific scientific questions. Recent advances in autonomous platform technology and the development of more informative and sophisticated instruments and techniques provide new unique observational and analytical capabilities. Yet, there seems to be a growing gap between our ability to make observations using the available technology and our capacity to interpret these observations for improved characterizations of the natural aquatic environments. This talk provides overviews of various aspects of phytoplankton fluorescence with an emphasis on the interpretation and better understanding of in vivo and in situ field measurements. INCREASED BIOLOGICAL CO2 UPTAKE FOLLOWING SEA-ICE RETREAT IN THE PACIFIC SECTOR OF THE ARCTIC OCEAN

The retreat of sea-ice into the Arctic Ocean basins in recent summers may have increased ocean biological production and uptake of atmospheric CO2. Reports of high pCO2 and decreased nutrient availability in the southern Canada Basin, however, suggested that marine productivity may have decreased and any enhancement of the Arctic Ocean CO2 sink short-lived. Contributing to this important debate, we report results from summer 2008 and 2010 during the Chinese Arctic Research Expeditions to the western Arctic Ocean basins up to 88°N. Our results revealed that a low pCO2 zone had formed in the rapid sea-ice melting areas (~80°N) but high pCO2, existed in the nearly ice-free southern basins, which were in contrast to the more uniform distribution observed under ice-covered waters in 1994. Evidence also suggested that high biological production and CO2 removal rates had followed the retreat of sea-ice, advancing from ~75°N in the 1990s and early 2000s to ~87°N in recent summers. These findings provide a more complete basis for predicting the Arctic Ocean’s response to future climate change. (Abstract ID 12033)

MODEL ASSESSMENT OF INUNDATION AT THE FUKUSHIMA DAI-ICHI NUCLEAR POWER PLANT FACILITY AND INITIAL SPREAD OF RADIONUCLIDES IN THE COASTAL OCEAN

A nested global-coastal FVCOM system has been used to investigate coastal inundation along northeast Honshu Island caused by the March 11 2011 earthquake. After successfully reproducing sea level recorded at coastal tidal gauges and measured inundation areas in the region, the model system was used to examine in detail the coastal flooding that led to major damage at the Fukushima Dai-ichi nuclear power plant facility and subsequent release of radionuclides into coastal waters and initial spread across the shelf into deeper water. With 5-m grid resolution around the facility, model results suggest that the breakwaters (designed to protect harbor in front of the facility from offshore waves) tended to guide the tsunami waves around the breakwaters and intensify flooding along the coast just to the north and south of the facility. The retreat of the flood waters appears to cause much of the damage to the facility. Model results show that the initial trajectories, dispersion and settlement of radionuclides released at the facility were influenced over the shelf by tidal flushing, wind driving and meso-scale features. (Abstract ID 10772)

SEASONAL VARIATION OF ORGANIC CARBON CONSUMPTION BY PLANKTONIC COMMUNITIES IN THE EAST CHINA SEA

Previous studies demonstrate that organic carbon consumption in the East China Sea (ECS) was high in summer, and the rate was significantly related to fluvial discharge from the Changjiang River. There is, however, rare data on this related issue in other seasons. In this study, we tend to evaluate and compare the seasonal variation of organic carbon consumption by planktonic communities (e.g., planktonic community respiration, CR) in the ECS. Results showed that the highest CR rate was found in spring and summer, and it was mainly attributed to higher planktonic biomass. This could be evidenced from the significant relationship observed between CR and particulate organic carbon (p < 0.001). Lower rate of CR was observed in autumn and winter. In addition to planktonic biomass, rate of CR during this period was also dependent on water temperature. Significant multiple linear regression observed between CR versus POC and temperature (p < 0.05) could support this assumption. Overall, our results suggest that planktonic biomass and temperature effect are needed to be considered when estimation of planktonic metabolism in the ECS. (Abstract ID 9810)
The importance of bottom topography in the dynamics of eddies and eddy-driven oceanic jets are examined here, using analytical and numerical techniques. The eddies and jets emerge as a result of baroclinic instability of a quasi-geostrophic zonal flow pertinent to this problem. Idealized topography has a form of a constant slope in the meridional and zonal directions, as well as an isolated meridional ridge. Analytical linear analysis demonstrates that even a small zonal slope can destabilize a flow that would be otherwise stable in the absence of topography. In contrast, the meridional slope can stabilize/destabilize a zonal background flow only through intensifying/weakening the background potential vorticity beyond a known critical value. The unstable modes have a shape of slanted "noodle" modes, whose spatial structure is further discussed in relation to the shape of topography. The nonlinear evolution of these growing modes leads to the formation of intensified oceanic jets. (Abstract ID 9900)

EDDIES AND JETS

This study describes characteristics of eddy heat and salt transports, in the basin-scale circulation as well as in the embedded mesoscale eddy found in the South China Sea. We first showed the features of turbulent heat and salt transports in mesoscale eddies using sea level anomaly data, in situ hydrographic data, and 375 Argo profiles. We found that the transports were horizontally variable due to asymmetric distributions of temperature and salinity anomalies and that they were vertically correlated with the thermocline and halocline depths in the eddies. An existing barrier layer caused the halocline and eddy salt transport to be relatively shallow. We then analyzed the transports in the basin-scale circulation using an eddy diffusivity method and the sea surface height data, the Argo profiles, and the climatological hydrographic data. We found that relatively large poleward eddy heat transports occurred to the east of Vietnam in summer and to the west of the Luzon Islands in winter, while a large equatorward heat transport was located to the west of the Luzon Strait in winter. The eddy salt transports were mostly similar to the heat transports but in the equatorward direction due to the fact that the mean salinity in the upper layer in the SCS tended to decrease toward the equator. Using a 2-layer reduced-gravity model, we conducted a baroclinic instability study and showed that the baroclinic instability was critical to the seasonal tendency to decrease toward the equator. Using a 2-layer reduced-gravity model, we conducted a baroclinic instability study and showed that the baroclinic instability was critical to the seasonal tendency to decrease toward the equator. PREY BACTERIAL SPECIES ORDER THE COMMUNITY STRUCTURE OF THEIR PREDATOR, BACTERIOVORAX

The role of predation in altering microbial communities has been studied for decades but few examples are known for bacterial predators. Bacteriovorax halophila, a prokaryote that preys on susceptible Gram-negative bacteria. Here we report the response of native Bacteriovorax to six prey. Water samples collected from Dry Bar, Apalachicola Bay were respectively spiked with indigenous Vibrio spp., Pseudoalteromonas spp., and Photobacterium spp. V. vulnificus and V. parahaemolyticus were included as reference strains. A clinical strain of V. vulnificus was also included to test strain-specific variations. At 24 hour intervals, optical density and abundance of Bacteriovorax were measured over five days. The predominant Bacteriovorax clones were selected and analyzed by 16S rRNA gene amplification and sequencing. The bacterial community parameters in shaping Bacteriovorax communities in aquatic systems. (Abstract ID 10842)

SOUTHERN HEMISPHERE EXTRA-TROPICAL FORCING ON ENSO - OBSERVATION AND MODEL COMPARISONS

The development of ENSO and its impacts on climate are well-known from the literatures, however, the origins of ENSO indeed remains unknown. Recently, two types of ENSO are further defined; Eastern-Pacific ENSO (EP ENSO) and Central-Pacific ENSO (CP ENSO), respectively. Recent studies indicate that they are driven by different driving mechanisms which require better understanding. Here, we discussed these driving mechanisms and how ENSO is generated resulting from the southern hemisphere extra-tropical influences. It is found that EP ENSO becomes more prominent since 1977 and leads EP ENSO for about 12 months with increasing correlation during the recent decades. Around two to three years before the occurrence of EP ENSO, warm Sea Surface Temperature anomaly (SST)) and negative Sea Level Pressure anomaly (SLP) propagate eastward from the Southern Pacific toward South America through the ocean-atmosphere coupled Antarctic Circumpolar Wave (ACW). In the tropic, the warm SSTa and negative SLPa also propagate eastward through the low-frequency component of Global ENSO Waves (GEW) and enhances the occurrence of EP ENSO. The evolving of ENSO after 1977 could be due to the large pattern changes of ACW and GEW after the 1976/1977 region shift. Further coupled model results show that the ACW indeed affects the occurrence of EP ENSO while there is no direct link with CP ENSO. (Abstract ID 11222)

NUMERICAL MODELING OF HYDRODYNAMICS AND SEDIMENT TRANSPORT OF NEW RIVER INLET (NC) USING NEARCOM-TVD

A new version of the Nearshore Community Model System (NearCoM-TVD) is utilized in this study to investigate hydrodynamics, sediment transport and morphological evolution of New River Inlet, NC. We focus on how the interaction between waves and strong tidal current near the inlet can change the pattern of wave and current fields and the resulting sediment transport. NearCoM version 4 was the main product in the NOAA Nearshore Community Model initiative in 2002. Since then, several enhancements to NearCoM has been made. The wave model SWAN was integrated with SHOREICIRC and the coupled model is also incorporated with large-scale forcing to expand its applicability to inner shelf and river/inlet (Shi et al. 2011, J. Geophys. Res., 116). Recently, SHOREICIRC is enhanced with a hybrid MUSCLE-TVD scheme and the resulting NearCoM-TVD is parallelized using MPI. To simulate the hydrodynamics of New River Inlet, the model is forced with tidal harmonic constants and offshore wave conditions. With a high grid resolution, the model predicts detailed flow structures and complex interactions between waves, currents, sediment transport and morphological evolution over a time-span of months. GEOCHEMICAL, SEDIMENTOLOGICAL, AND STRATIGRAPHIC REFLECTIONS OF A LATE CAMBRIAN GLOBAL PALEOCEANOGRAPHIC EVENT

A Late Cambrian global paleoceanographic event has been indicated by a trilobite mass extinction and a worldwide positive excursion in marine carbon isotope records in phase with an excursion in sulfur isotope records. This paleoceanographic event was possibly accompanied with a global change in paleoclimate and eustasy which was partly evinced by sedimentological and stratigraphic study. The present study shows high-resolution geochemical, sedimentological, and stratigraphic evidence of the perturbation in carbon isotope values, faunal assemblages, and relative sea level in the North China Platform—a vast epeiric platform (ca. 1500 km east-west and 1000 km north-south). A well-correlated (ca. 100 km in distance) truncation surface of a strongly deformed limestone bed, missing of a trilobite bionome (Prochuanxia), and an abrupt increase in carbon isotope value collectively indicate a significant hiatus in the succession. Preliminary intra- and interplatform correlations of the sedimentological and stratigraphic feature across this event zone suggest possible global cooling and eustatic fall during the middle to late Cambrian of the greenhouse period. (Abstract ID 9600)

DATA-ASSIMILATIVE MODELING INVESTIGATION OF GULF STREAM WARM-CORE RING INTERACTION WITH CONTINENTAL SHELF AND SLOPE

A coastal data assimilation system was constructed based on Regional Ocean Modeling System (ROMS) Incremental Strong constraint 4D Variational (IS4DVAR) data assimilation algorithm. The model (MARGOM) encompassing coastal ocean in Northeast US assimilates satellite observed sea surface height and sea surface temperature, in-situ temperature and salinity profiles from expendable bathythermograph, Argo floats, CTD stations and glider transects. Two-month continuous assimilation experiment was performed over April-May 2006 to simulate the evolution of a large Gulf Stream Warm Core Ring (WCR) event. The data assimilative MARGOM model well reproduced the temporal and spatial variations of this WRC. Interaction of WCR with continental shelf and slope induced significant offshore transport and altered the shelfbreak frontal system dramatically. Eddy induced water transport and its associated biological implication are further investigated using an idealized biological model simulation. (Abstract ID 11272)

CSEOE GOES INTERNATIONAL: CSEOE CHINA

The Centers of Ocean Sciences Education Excellence (CSEOE) has formed a national US network of scientists, educators, and facilitators that promote ocean literacy and a broadening of the impacts of ocean research. Following the idea of “One World, One Ocean”, CSEOE has begun to extend its network internationally. A CSEOE China Planning workshop, held in March 2010 in Beijing, China, brought together ocean scientists, students, CSEOE representatives and government officials to exchange information focused on ocean science education in the United States and China and to explore the possibility of establishing a Center for Ocean Science Education Excellence in China. Following the two-day workshop, US delegates visited Xiamen University in Xiamen and Ocean University in China in Qingdao. The State Oceanic Administration of China supported the subsequent development of CSEOE China, a network which now includes 12 leading ocean institutions in China. Continuing networks of graduate students and faculty, inclusion of CSEOE China into the CSEOE Network, and translation of the Ocean Literacy documents into Chinese are some examples of international cooperation that could broaden to other countries worldwide. SOURCES OF OUTWELLED DISSOLVED ORGANIC MATTER IN SALT MARSHES

An observation network has been deployed in Snipe Creek, FL, to estimate dissolved organic carbon (DOC) and chromophoric dissolved organic matter (CDOM) sources and fluxes from a pristine, shallow salt marsh in the Big Bend region of Florida. Snipe Creek drains approximately 2.5 km2 of salt marsh with average daily tidal variations of about 1 meter. Continuous monitoring of CDOM along with discrete measurements of DOC suggest that small variations in tidal height result in factor of two differences in the up-creek endmember. Rapid in-mash processing by bacterial and photodegradation processes as well as widely varying drainage areas lead to different export fluxes during each individual ebb tide. Additionally, incubations of creek water exposed to natural sunlight suggest that 10-25% of the creek DOM could be due to photodissolution of respaced sediments. Overall, high temporal and spatial resolution measurements of DOM in Snipe Creek suggest that a sea-level rise as small as 1-2 centimeters could lead to a large change in the quantity and quality of outwelled DOM to coastal waters. INTERPRETING THERMOCLINE STRIATIONS IN THE SUBTROPICAL GYRE FROM THE PERSPECTIVE OF MIXING/TRANSPORT, AND THE ENERGY SPECTRUM

Thermocline striations in the subtropical gyre are embedded in the large-scale gyre-structured mean flow. In previous work (Chen, thesis in preparation), a simple theoretical model was developed and used to investigate mechanisms for striation formation in a subtropical gyre. Eddies propagating in fixed directions produce kinematic striations, and the same mechanisms describes striation formation in the realistic ECCO2 state estimate. Here the questions are posed as to whether striations are, at least in part, components of the eddy field appearing in regions of the variability frequency-wavenumber spectrum, and whether they are also dynamical quantities with mixing and transport contributions. A randomly forced barotropic quasi-geostrophic model having an arbitrary constant mean flow imposed is used. Striations are bands in the low-frequency component of the eddy field, align with the eddy propagation direction, and exchange energy with the high frequency eddies. Depending on the mean flow direction/magnitude/stratification, striations can be identified either with the jets described by Rhines, or as bands produced by small eddies propagating in fixed directions. These questions are also being investigated in a 1.5 layer model with a subtropical gyre and in the ECCO2 state estimate. (Abstract ID 10028)

ACROSS-STREAM MOMENTUM BUDGET OF POSITIVELY AND NEGATIVELY BUOYANT RIVER OUTFLOWS

The rapid spreading and mixing in the near-field region of river plumes have profound influences on the far-field plume evolution. Yet, the dynamics as the plume transitions from a near-field inertial jet and far-field geostrophic currents remains poorly understood. In this study, we use a 3D hydrodynamic model (ROMS) to investigate the across-stream momentum budget along the plume streamlines on sloping shelves. Both positively (hypopycnal) and negatively buoyant (hyperpycnal) plumes are considered. The hyperpycnal cases are motivated by outflows of mountainous rivers which occasionally have enough sediment to be denser than the ambient seawater. It is found that the layer-averaged, across-stream momentum balance of positively buoyant plumes is cycle-geostrophic: a balance between Coriolis, centrifugal, and pressure gradient forces. In the near-field, the balance is principally between centrifugal and pressure gradient, whereas in the far-field the flow approaches the geostrophic balance. The transition appears to coincide with an along-stream location beyond which the flow switches from critical to sub-critical. For negatively buoyant plumes, before the plumes divide as undercurrents, the across-stream momentum balance is between pressure gradient and centrifugal, just as in surface plumes. In the far-field where the plume hugs the sea-floor, bottom friction dominates the across-stream momentum budget (Ekman balance), and an ageostrophic secondary circulation is evident. MULTI-DECADAL SEA LEVEL AND GYRE CIRCULATION VARIABILITY IN THE NORTHWESTERN TROPICAL PACIFIC OCEAN

Sea level rise with the trend > 10mm/yr has been observed in the tropical western Pacific Ocean over the 1993–2009 period. This rate is three times faster than the global mean value of the sea level rise. Analyses of the satellite altimeter data and repeat hydrographic data along 137ºE reveal that this regionally enhanced sea level rise is thermosteric in nature and vertically confined to a patch in the upper ocean above the 12 deg C isotherm. Dynamically, this regional sea level trend is accompanied by southward migration and strengthening of the North Pacific Current (NEC) and North Pacific Countercurrent (NECC). Using a 1.5 layer reduced-gravity model forced by the ECMWF reanalysis wind stress data, the authors find that both the observed sea level rise and the NEC/NECC's southward migrating and strengthening trends are largely attributable to the upper ocean watermass redistribution caused by the surface wind stresses of the recently strengthened atmospheric Walker circulation. Based on the long-term model simulation, it is further found that the observed southward migrating and strengthening trends of the NEC and NECC began in the early 1990s. In the two decades prior to 1993, the NEC and NECC had weakened and migrated northward in response to a decrease in the trade winds across the tropical Pacific Ocean. (Abstract ID 12276)

MULTI-SCALE COUPLED OBSERVATIONS AND MODELING OF TYPHOON FANAPI (2010)

The goal of ITOP/TCS10 is to better understand and predict TC formation and intensity change through a comprehensive observation of TC structure and its oceanic and atmospheric environment over a broad spatial and time scales. Typhoon Fanapi provided a perfect opportunity to study the entire evolution from a tropical depression to a typhoon. An objective cloud-cluster tracking method is used to identify the TC precursor clusters leading up to the initial formation of the TD and later becomes Typhoon Fanapi. Using hourly satellite IR images, the ITOP/TCS10 field experiments were designed to follow the developing TC through its lifecycle with extensive observations of pre-, during- and post-TC oceanic and atmospheric conditions. More than 800 GPS dropsondes and 900 AXBTs/AXCTs as well as drifters and floats were deployed in TCs from August-October 2010, including Typhoon Fanapi. A unique observation in Typhoon Fanapi is the development of a stable boundary layer in the near-storm cold wake region. The coupled model forecasts show that the near surface air in the stable boundary layer tends to penetrate further inward into the TC inner core region and eyewall than the air in unstable and neutral boundary where some high theta-e air goes into rainbands. It indicates that the cool-SST induced stable boundary may have a direct impact on TC structure and intensity. Observations and a combined tracer and trajectory analysis in the coupled model will be presented. (Abstract ID 12868)

VIRUSES INFECTING FRESHWATER FILAMENTOUS CYANOBACTERIA REPRESENT A PREVIOUSLY UNRECOGNIZED EVOLUTIONARY LINEAGE OF CYANOPHAGES

Cyanobacteria and their phages are important members of aquatic systems. However, very little is known about the genomic diversity of phages which infect other cyanobacteria, outside the Synechococcus and Prochlorococcus genus. Here, we sequenced the genome of two cyanomyophages, A-1(L) and N-1, infecting the freshwater filamentous heterocyst-forming cyanobacteria Nostoc sp. PCC7120, Notoce sp. PC7210. Their genomes exhibit no similarity with previously sequenced cyanophages and the majority of their predicted genes have no detectable homologues. Many predicted genes with known functions are highly similar to those in filamentous cyanobacteria, for example, they contain a distinct DNA polymerase B closely related to those found in plasmids of the cyanobacteria Cyanothece sp. PCC7428, Notoce sp. PCC7120 and Anabaena variabilis ATCC29413. Together these polymerase sequences form a
distinct group which is more related to the substantial proto-bacterial DNA polymerase group than to other viral DNA polymerases, suggesting it was acquired from a proto-bacterial by a phage and then transferred to the cyanobacterial plasmid. The sequencing of these cyanophages has demonstrated that over evolutionary time gene transfers have forged the genetic makeup of cyanophages and their Nostoc hosts. (Abstract ID 116820)

OCEAN MIXING AND AIR-SEA HEAT FLUXES CAUSED BY TROPICAL CYCLONES ON BASIN AND ANNUAL SCALE

As a strong heat engine of the ocean, tropical cyclones provide an effective mechanism to transport heat, mass and nutrient in the ocean. Evidence indicates that these relatively small scale and transient events can influence larger scale dynamical processes in both the ocean and atmosphere. However, a clear understanding of tropical cyclones’ climate impacts, such as vertical mixing in the ocean, and air-sea heat fluxes, are limited by lack of all-weather-in-situ observations with sufficient horizontal, vertical and temporal coverage and resolution. In this study, for the first time, we use global covering, vertical resolving Argo profiling data to estimate the cumulative effects of tropical cyclones by analyzing the vertical thermal changes down to 2000 meters before and after storm passages during 2004-2011 period. We estimate climatologies of both ocean mixing and net air-sea heat fluxes induced by tropical cyclones. Our results show strong subsurface mixing (up to 200m depth) and main thermocline mixing (400-800m) that presents much deeper ocean mixing than previous assumptions. This strong mixing in ocean pumps about 0.81 PW heat downward from surface to deeper ocean. In addition, tropical cyclones convey about 1.0 PW heat annually from the ocean to the atmosphere, equal to about 9.1 W/m2, which accounts for about 10% of the global ocean heat budget. It suggests tropical cyclones provide a viable mechanism to close the ocean heat budget. (Abstract ID 98080)

ESTUARINE RESPONSE TO SEA-LEVEL RISE: A NUMERICAL STUDY OF CHESEPAKE AND DELAWARE BAYS

Global sea-level has risen at a rate of 1.6 mm/yr during the past half century and is expected to increase at a substantially greater rate during the 21st century. The rising of sea-level affects salinity structure and circulation in estuaries. Sea-level rise tends to lead salt intrusion into estuaries, therefore increasing stratification. On the other hand, however, sea-level rise also likely leads to a larger tidal range, therefore increasing tidal mixing. The competition between the two responses determines the influence of sea-level rise on estuarine stratification. Estuarine circulation relies on along-estuary density gradient and vertical mixing, hence, indirectly responses to sea-level rise. To understand the influences of sea-level rise on estuarine physical processes, we have developed a numerical model using FVCOM and will carry out a series of process-oriented numerical experiments. The model domain covers Chesapeake and Delaware Bays and part of middle Atlantic Bight. Since the Chesapeake and Delaware Bays are two common types of estuaries, comparisons of the two estuaries will help gain insights into the effects of climate change on estuarine physical processes in general. ASSESSING ATLANTIC OVERTURNING CIRCULATION (AMOC) IN CMIP5 MODELS

Meridional mass transport streamfunctions from CMIP5 models presently available at PCMDI data server are examined. Measured by maximum overturning streamfunction at 30N, most models do not show a significant trend of AMOC in their historical simulations (1850-2005). Moreover, the spread of AMOC amplitudes across models is narrowed compared to CMIP3 runs, even though the spread is still larger than internal variability of any one particular model. With the exception of one model, the simulated mean AMOCs averaged between 1850 and 2005 by all models are within the observational range of 11-22 Sv. Under “representative concentration pathways” RCP2.6 and RCP4.5 forcing scenarios, all models show a decrease of AMOC. In the first half of the 21st century, but the majority of the models also indicate a rebound of AMOC starting in mid century around 2060, BEFORE the radiative forcing peaks at 2100. This recovery is more robust under RCP2.6 forcing than under RCP4.5 forcing, and the rate of recovery is also faster in the former. All available models show a continuous decrease of AMOC throughout the 21st century under RCP8.5 forcing; in the case of RCP8.5 forcing, the rates of decrease are similar across all models (only one model provides RCP8.5 forcing output). A few models have extended runs to year 2300 where the radiative forcing stabilizes after year 2100, all these runs show a slow recovery of AMOC after 2100. (Abstract ID 116825)

INTERANNUAL VARIABILITY OF HIGH-WIND OCCURRENCE IN THE SOUTHERN INDIAN OCEAN

High winds (>20m/s) pose great danger for navigation and are important for surface fluxes and ocean mixing. In this study, interannual variability of high-wind occurrence in the Southern Indian Ocean is investigated based on observations from the satellite-borne Special Sensor Microwave Imager (SSMI). Climatology maps show that high wind frequency (HWF) is the highest in boreal summer, and is close to zero in boreal winter. Remarkable interannual variability of summer HWF is found on the warm flank of Subantarctic front between 50°-90°E (CSAF99) and off southern tip of Africa (SF). On interannual scales, HWF in SF region (subpolar region) has significant negative (positive) correlation with the southern annular mode index. During a positive SAM phase, decreases (increases) in the mean westerlies cause HWF to decrease in SF regions (subpolar region). In the vicinity of the SAF, HWF is significantly correlated with the difference between sea surface temperature and surface air temperature (SST-SAT), indicative of the importance of atmospheric instability. Cross-frontal wind and an SST gradient are important for the instability of marine atmospheric boundary layer on the warm flank of the SST front. In addition to distinct interannual variability, HWF in the SAF region also presents remarkable decadal variability. (Abstract ID 96703)

A 3D EULERIAN-EULERIAN TWO-PHASE MODEL FOR SEDIMENT TRANSPORT

Significant research efforts have been made in modeling sediment transport using a two-phase flow approach. However, existing models are limited to one-dimensional-vertical (1DV) for wave-induced transport or two-dimensional-vertical (2DV) for steady flow. These models are also based on a Reynolds-averaged approach for turbulent flow and hence turbulence-sediment interactions cannot be resolved. Moreover, processes such as bedform dynamics and plug flow cannot be captured with a 1DV model. Here, we develop a 3D two-phase model to investigate sediment transport driven by combined wave and current flows. The numerical model is based on a four-way coupled Eulerian two-phase flow formulation with appropriate closure on particle stresses. At a first step, more efficient 2D/3D Reynolds-averaged approach with a k-ε turbulence closure is adopted to model bedform migration and plug flow driven by oscillatory flow. Model results are validated with published data in steady channel and U-tube flows. Model results are also compared to recent video observations from U-tube experiments performed at the Naval Research Laboratory using nycor (-1.17) sediments that demonstrate the generation of plug flow around flow reversal under sheet flow conditions. TRACKING ANOMALOUS SEA SURFACE TEMPERATURE VARIABILITY OF THE NORDIC SEAS, 1982-2010

We are interested in using satellite SST to track conditions in the Nordic Seas region of the North Atlantic because of the existence of a multi-decade long record (1982-2010) with good spatial coverage. Here we begin by evaluating Pathfinder version 5 remotely sensed infrared SST in comparison with two SST analysis products and with in situ observations. We identify and remove biases including a -0.35C for SST < 40C and a positive bias for lower temperatures. The corrected SST shows a warming trend over the nearly 40-year period in all ice-free regions north of 50DN, but is highest in the Labrador Sea. There is a clear relationship between SST and 0/300m heat content on interannual time scales for three regions: western North Atlantic, Nordic and Barents Seas. The highest correlation between these variables of 0.88 occurs in winter in the Barents Sea. In the Nordic Seas interannual correlations (stratified seasonally) vary from 0.75 in winter to 0.69 in summer. A detailed examination of the SST data reveals a slow counterclockwise propagation of SST anomalies in the Nordic Seas and to the north in the Barents Sea with an approximate timescale of 7-8 years. Possible causes of this striking feature will be discussed. (Abstract ID 11178)

A COMPARISON OF RECENT OBSERVATIONS IN DRAKE PASSAGE FROM THE CDRAKE EXPERIMENT TO THE SOUTHERN OCEAN STATE ESTIMATE
Accurate model simulation of the ocean requires reproducing several metrics, including ocean heat content, geopotential height, mass transport, and eddy kinetic energy. We use observations from the recent cDrake experiment to evaluate the representation of these metrics in the Drake Passage in a Southern Ocean state estimate (SOSE). The observations consist of near-bottom currents, bottom pressure, and round-trip vertical acoustical travel time between sea floor and sea surface from an array of bottom-moored Current and Pressure-recording Inverted Echo Sounders (CPIES) deployed from 2007 to 2011, as well as hydrography and direct velocity observations from multiple cruises. The cDrake transport line (21 CPIES) spans 800 km across Drake Passage. The cDrake local dynamics array (21 CPIES) has spatial resolution sufficient to capture mesoscale eddies within the region of maximum surface variability between the Subantarctic and Polar Fronts. The SOSE is an eddy-permitting version of the MITgcm which is least-squares fit to ocean observations using the adjoint method. The independent cDrake observations are used here to evaluate the state estimate in Drake Passage prior to assimilation. (Abstract ID 10654)

THERMAL IMAGING OF THE SURFZONE DURING SURF ZONE OPTICS

In the nearshore and surfzone, significant progress has been made in understanding EO and radar signatures, but thermal infrared remote sensing is generally unused and consequently untested. However, the sea surface in the nearshore is rich in observable natural temperature variation directly related to dominant physical processes including waves, wave breaking, turbulence, and currents. In September 2010, thermal imaging cameras mounted on fixed and airborne platforms were used to observe surfzone processes at the Field Research Facility on Duck NC as part of the Surf Zone Optics (SZO) and Data Assimilation and Remote Sensing for Littoral Application (DARLA) experiments. Preliminary analysis showed expected observable signals primarily waves made visible by the slope modulatation of emissivity and reflectivity, thermally bright breaking wave crests, and disturbance of the thin surface thermal layers by turbulence and wave breaking. However, unexpected signatures were observed, including rapid cooling of residual foam left by breaking waves. In addition to analysis of these thermal signatures, we will demonstrate initial application of thermal imaging to estimate large-scale surface currents, wave field properties, and wave breaking. ACCURATE AND PRECISE DETERMINATION OF TROPHIC POSITION OF ORGANISMS BASED ON NITROGEN ISOTOPIC COMPOSITION OF AMINO ACIDS

Knowledge of the trophic position (TP) of organisms in food webs allows understanding of biomass flow and trophic linkages in complex networks of ecosystems. Stable isotope analysis of amino acids is a new method with the capability to estimate trophic position of various organisms in food webs. This approach is based on contrasting isotopic fractionation during metabolic processes between two common amino acids: glutamic acid (Glu) shows significant 15N-enrichment...
of +8.0 permil, whereas phenylalanine (Phe) shows little change in d15N values (by +0.4 permil). Recently, we established a number of natural and laboratory grown organisms a general equation for the estimation: TP = [(d15NGlu – d15NPhe + b)/7.6 + 1] where b represents the isotopic difference between Glu and Phe in primary producers (~3-4 permil for aquatic cyanobacteria and algae, +8.0 permil for terrestrial C3, and ~0.4 permil for terrestrial C4 plants).

In the presentation, we briefly review this new method and show its application to natural organisms in aquatic and terrestrial food webs. (Abstract ID 10118)

LANGMUIR CIRCULATION: AN AGENT FOR VERTICAL RE-STRAFFICATION?

The impact of surface waves on the stability of submesoscale lateral fronts in the ocean surface boundary layer is investigated using the stratified, rotating Crag-Leibovich (CL) equations. Through the action of the CL vortex force, down-front propagating surface waves fundamentally alter the super-inertial, two-dimensional (down-front invariant) linear stability of these fronts, with the classical symmetric instability mode being replaced by a hybrid Langmuir-circulation/symmetric mode. The hybrid mode is shown to exhibit much larger growth rates than the pure symmetric mode, to exist in a regime in which the vertical Richardson number is greater than one, and to accomplish significant cross-isopycnal transport. Non-hydrostatic numerical simulations reveal that the nonlinear evolution of this hybrid instability mode can lead to rapid, i.e. super-inertial, vertical restratification of the mixed layer. Remarkably, Langmuir circulation – generally viewed as a prominent vertical mixing mechanism in the upper ocean – may thus play a pivotal role in mixed layer restratification. (Abstract ID 11319)

MODELING OF HYPOXIA FORMATION IN YEONGSAN RIVER ESTUARY, KOREA (USING 3-D MODEL)

Recurrent hypoxic or anoxic conditions in the bottom water during the summer have been posing threats to the ecosystem health in Yeongsan River estuary, Korea, since the construction of a sea wall in 1981. As a part of developing integrated estuarine management system, mechanisms of hypoxia formation were captured using a 3-D hydrodynamic-water quality model EFDC/Environmental Fluid Dynamics Code describing phytoplankton-DO-C-N-P-Si coupled cycle and particle movement. Analysis of particle movement calculated along the bottom of the narrow estuary toward the sea wall by high oxygen consumption, toward the hypoxic area near the sea wall due to estuarine circulation in summer rainy season. The concentration of dissolved oxygen decreases rapidly as the oxygen rich coastal water flows along the bottom of the narrow estuary toward the sea wall by high oxygen consumption, which is related with severe organic enrichment of the bottom water sediment. Formation of hypoxic conditions is thus closely related with the timing and the amount of freshwater discharge from the sea wall. (Abstract ID 12622)

DETERMINATION OF TROPHIC LEVEL OF BENTHIC ORGANISM AND FISHES IN SOMJIN ESTUARY, KOREA

This study was conducted to identify the food web structure in Seonjin Estuary using d13C and d15N isotope ratio. d13C of benthic macro invertebrates living in Seonjin estuary were classified into two groups. Deposit feeders such as Macroth主编illum abbreviatus and Macroth主编illum japonicus showed relatively enriched carbon isotope ratios than filter feeders such as Crassostrea gigas and Cyclina sinensis. In terms of iso-source mixing model, the main diet source of Macroth主编illum abbreviatus was seagrass while main diet source of Crassostrea gigas was POM. d15N of benthic macro invertebrates exhibited small variation between species except polychaete spp. Distribution of d13C of fish was similar to d13C of benthic macro invertebrates and d15N were more enriched than benthic macro invertebrates. We concluded that both POM and seagrass are important diet source for benthic macro invertebrates and fish in Seonjin estuary. In addition, the trophic levels of organisms living in Seonjin estuary are compared by nitrogen isotope ratios of individual amino acids (etc. phenylalanine and glutamic acid). (Abstract ID 11000)

SURFACE GEOSPHERIC CURRENT ESTIMATED FROM ALTIMETER AND SURFACE DRIFTER DATA IN THE JAPAN/EAST SEA

In order to estimate surface geospheric currents in the Japan/East Sea mean dynamic topography (MDT) was calculated from the steric height relative to 500 dbar and surface drifter dataset. Sea level anomalies (SLA) were derived from the satellite altimeter data and, then, SLA data were added to MDT to make absolute dynamic topography (ADT). Surface geospheric currents were calculated from the ADT from 2002 to 2005. Accuracy and characteristics of the estimated surface geospheric current were analyzed. Correlation coefficients between the satellite altimeter-derived surface geospheric currents and surface currents estimated from surface drifter trajectories were 0.71 and 0.72 for the eastward (u) and northward (v) velocities, respectively. Correlation coefficients between the satellite altimeter-derived surface geospheric currents and surface currents measured by ship-mounted ADCP in the western part of Ulleung Island were 0.61 and 0.52 for u and v, respectively. Correlation coefficients between the satellite altimeter-derived surface geospheric currents and bottom-mounted ADCP between Ulleung Island and Dok Island from 2002 to 2004 were 0.75 and 0.70 for u and v, respectively. INTERACTIONS BETWEEN OSMOTIC STRESS AND DARK-INDUCED CELL DEATH IN THE HALOTOLERANT UNICELLULAR CHLOROPHYTUM DUNALIELLA TERTIOLECTA

The unicellular chlorophyte alga, Dunaliella tertiolecta can tolerate a broad range of salinities from below 0.05 M (3 ppt) to above 5 M NaCl (300 ppt): virtually the solubility limit of NaCl by accumulating glycerol and lipids as compatible solutes. We studied interactions between salinity and cell death induced by the stress of light deprivation by monitoring physiological and biochemical responses. At 4 X normal sea water salinity (1.6 M NaCl), D. tertiolecta survived more than twice as long in darkness as at normal salinity, and showed more gradual declines of photosynthetic capability (Fv/Fm). No indication of cell lysis (declines in cell numbers or particulate C) or increases in caspase-like protease activities (associated with programmed cell death) were observed. The same results were seen with an equivalent osmotic shock using sorbitol, indicating the prolonged survival is due to osmotic rather than ionic components of salt stress. Although the mechanism of cell death suppression is unknown, it offers a tool to dissect cell death pathways and may be of relevance in understanding the prevalence and significance of cell death in species that live in environments like estuaries where salinity varies. INFLUENCE OF FRESHWATER INFLOWS ON THE NUTRIENT DYNAMICS AND WATER QUALITY IN YEONGSAN RIVER ESTUARY, KOREA

Changes in freshwater inflows and hydrodynamics after the construction of a seawall in 1981 have significantly affected the water quality and recurrent hypoxia in the bottom water has been posing threats to the ecosystem health in the shallow macrotidal Yeongsan River estuary, Korea. In addition, Yeongsan River estuary is subjected to further modifications in freshwater inflows and hydrodynamics after the construction of a seawall in 1981. Nutrient fluxes & budgets in different freshwater inflow conditions were discharges were analyzed, and short-term responses following freshwater discharges were monitored several times from June 2010 to September 2011. Clear increase of nutrient and organic matter concentrations was detected during high inflow periods especially in summer. Signals of freshwater inflows lasted several days showing a gradient from the seaward toward the mouth of the estuary. Nutrient fluxes & budgets in different freshwater inflow conditions were calculated using a mass balance model. (Abstract ID 11059)
more than 95% appearance in most stations. Opportunistic species such as agglutinated foraminifera were increased. Temporal improvement of the pollution after the flooding residual flow is showed at the shallow depth during spring period. The residual flow was changed, due to barotropic forcing with river discharge and long-term tidal components. (Abstract ID 12846)

THE SPATIAL AND TEMPORAL VARIABILITY OF SURFACE PCO2 IN THE WESTERN NORTH PACIFIC AND THE EAST CHINA SEA DURING 2006–2010

We examined the spatial and temporal variability of partial pressure of CO2 (pCO2) in surface seawater in the western North Pacific and the East China Sea based on surface pCO2, temperature and salinity continuously measured on board R/V Onnuri in September 2006, October 2007, and June 2008, 2009 and 2010. The western North Pacific and the East China Sea were distinguished in not only sea surface temperature and salinity but also pCO2 distributions. The surface pCO2 showed higher values in the lower latitude (the western North Pacific) than those in the higher latitude (the East China Sea) in wide ranges. In the western North Pacific, the seasonal and interannual variations of surface pCO2 distributions were small. On the contrary, those were wide and significant in the East China Sea. The western North Pacific acted as a weak or moderate source of CO2, of which fluxes ranging from 0.07 to 0.48 mmol m-2 day-1 at all times. However, the East China Sea acted as a sink of CO2 in both spring and summer. The fluxes ranged from -0.45 to -6.11 mmol m-2 day-1. (Abstract ID 11005)

OCCURRENCE OF HYPOXIA AND ROLE OF OXYGEN DEMAND IN WATER COLUMN AND SEDIMENT IN YEONSAN ESTUARY

Vertical distribution of temperature, salinity and dissolved oxygen (DO) concentration were measured to verify the spatial and temporal variability of suboxic or hypoxic water at the Yeongsan estuary of Korea peninsula in July and September of 2011. Intact sediment cores and bottom water samples were taken for bottom water oxygen demand (BWOD), sediment oxygen demand (SOD) and denitrification measurement. In July when the freshwater input was high, strong vertical stratification was observed, but vertical segregations of DO concentration were not evident. In September when freshwater input was low, degree of stratification was low, but DO concentration rapidly decreased within the top 5m. In particular, bottom water DO concentration in near of the dam was relatively lower than other sites. The BWOD was higher near the Yeongsan Dam and generally decreased seaward. Suboxic condition occurred near the Yeongsan Dam seems to be the result of high BWOD and SOD as well as the limited water movement in the site. (Abstract ID 12744)

THE DISPERSION OF RADIOACTIVE WATER RELEASED FROM THE FUKUSHIMA DAIICHI NUCLEAR POWER-PLANTS

We use a numerical model to investigate the dispersion of radioactive water released from the Fukushima Daiichi Nuclear Power-plants (FDNP) on March 2011. The numerical model is based on a three dimensional particle random-walk model and a z-coordinate ocean general circulation model developed at the Earth Simulator Center, JAMSTEC. Radionuclide concentrations are obtained from the density of particles per unit volume water. Experiments have been carried out for 157Cs for 4 months and the results show that coastal currents and meso-scale open oceanic eddies having large influence on the behavior of the radionuclides. The radionuclides in coastal currents remain along the coast where the one in meso-scale open oceanic eddies rapidly escape to the interior of the Pacific along the Kuroshio extension. The seaward radionuclides deeply penetrate into the deep layer corresponding to the deepening of the mixed layer of the Kuroshio. (Abstract ID 11025)
VIRAL CONTROL OF AUTOTROPHIC VS. HETEROTROPHIC BACTERIA IN THE SURFACE OCEAN: ECOLOGICAL NETWORKS LINKING VIRUSES AND BACTERIA

Identifying relationships in complex communities drives our ecological understanding of the natural world. We investigated top-down controls, specifically myxoviruses, of bacterial community structure. The myxovirus superfamily is diverse, typically accounts for ~60% of the viral community in surface water, has a broad host range, and is detectable through cultivation-independent means. Samples for DNA and auxiliary measures were collected at USGS Microbial Observatory at the San Pedro Ocean Time-series station. Community structure was analyzed by: ARISA for bacteria and g23 TRLFP for myxoviruses. We examined a 3 year time-series (3/2008-1/2011) to determine principal drivers of community shifts and how their relative importance may vary over time. We also examined coherence between relationships from 5m and chlorophyll maximum depths. Correlational analyses yield networks that are inherently complex yet can provide insight on viral controls of bacteria for which no cultured phages are currently known to exist, such as SAR11. Through our network and time-series analysis, we can indicate key clusters of important factors - as it is unlikely that a single parameter controls microbial communities. (Abstract ID 10119)

GLOBAL COMPARISON OF TROPHIC POSITIONS OF MESOPELAGIC MYCTOPHIDS AND STOMIIDS USING AMINO ACID NITROGEN ISOTOPIC ANALYSES

We examined the biogeographical and ecological mechanisms responsible for variability in bulk and amino acid (AA) stable nitrogen isotope compositions in two important mesopelagic fish families, Myctopidae and Stomiidae, from five globally distributed regions. Using the δ15N values of individual AAs we quantified trophic positions (TPs) of these fishes. Despite variability in bulk tissue δ15N values, TPs are nearly uniform within both families of fishes across all regions. Differences in the bulk and AA δ15N values reflect region-specific water mass biogeochemistry controlling δ15N values at the base of the food web and these differences are inherited by the fishes analyzed. TPs calculated from AA isotopic analyses for myctophids (TP ~2.9) approximate expectations from stomach content (SC) studies describing these fishes as zooplanktivorous (TP ~3.2). In contrast, TPs calculated from AA analyses for stomiids (TP ~3.2) were lower than expected given previous SC studies, which report that stomiids are piscivorous (TP ~4.1) across all regions. Our TP estimates suggest that stomiids are more similar to myctophids and are not strict piscivores, calling for possible reevaluation of the trophic roles of these fishes. (Abstract ID 10769)

COMPOUND SPECIFIC STABLE CARBON ISOTOPE ANALYSIS OF AMINO ACIDS IN BONE COLLAGEN TO RECONSTRUCT HUMAN PALAEODEITIS USING LC-IRMS

Compound-specific carbon isotopic analysis of amino acids in bone collagen is a valuable tool for the reconstruction of human palaeodietics. The recent development of coupling liquid chromatography to IRMS enables online carbon isotope ratio measurement of amino acids without adding extra carbon to analytes. We used LC-IRMS techniques to measure the 613C values of amino acids in bone collagen of humans (n = 9) and animals (n = 27) from archaeological sites. The isotopic results revealed that human and faunal species in the sites had similar patterns in both EAAs and NEAAs. All amino acids in marine animals were 13C-enriched relative to those of the terrestrial animals. The average marine-terrestrial 613C offset was 6‰ in EAA and 8‰ in NEAA. The 613C isotopic differences in amino acids between two faunas were the largest for glycine and serine (NEAA) and the smallest for phenylalanine (EAA). Threeeine among the EAAAs had a large difference (~8‰) in 613C values. These amino acids can be possible new isotopic markers that he used to distinguish between marine and terrestrial diets in palaeodiетics. (Abstract ID 10474)

SURFACE WAVE MEASUREMENTS USING SHIP MOUNTED ULTRASONIC ALTIMETER

Experimental studies of surface wave effects on air-sea fluxes and ocean circulation require accurate measurements of the waves. We present a robust new method for measuring 1D surfac e wave spectra using ship mounted ultrasonic altimeter combined with an accelerometer. The altimeter is mounted at the bow of the ship and used when the ship is on station facing the wind and the waves. The accelerometer is used to correct for ship motion. We present results from two recent field studies. The results are compared both with data from a conventional wave ridge buoy and wave model analyses when direct observations are not available. We find good agreement with regard to integrated parameters such as significant wave height and also with regard to spectral shape. (Abstract ID 10981)

STABILITY OF CADMIUM COMPLEXES WITH THE SIDEROPHORE DESFERRIOXAMINE B (DFOB), a group of organic ligands that facilitate uptake of the micronutrient Fe(III) but also form very stable complexes with many divalent metals. Stability constants of bidentate, tetradentate, and hexadentate Cd–DFOB complexes were determined by potentiometric titration in a non-complexing medium (NaClO₄) at seawater ionic strength. Non-linear regressions of the data were performed with FITEQ, a program that has been used to interpret the observed precipitation of a polynuclear complex at high Cd:DFOB ratios. The stability constant of the mononuclear bidentate Cd–DFOB complex was found to be log α = 7. Subsequent modeling with MINEQL showed that, even in the absence of Fe(III), DFOB complexation has no effect for Cd uptake in the upper ocean. (Abstract ID 9626)
and high freshwater inflows, and the effects on salinity intrusion are quantified. Rising sea levels reduce the impact of bottom-generated turbulence causing less vertical mixing. The increased flow depth also creates stronger gravitational circulation and higher vertical stratification. When coupled with reduced vertical mixing, this results in enhanced salinity intrusion in North San Francisco Bay. While higher sea levels lead to more salinity intrusion, the relative effect of sea-level rise is greatest under low flow conditions owing to the predominance of vertical mixing when the vertical stratification is weakest. These effects are quantified through power-law fits relating the salinity intrusion length, X, to changes in sea-level and flow rate. The power laws are used to determine necessary flow rates to maintain current salinity standards under the different sea-level rise scenarios. (Abstract ID 9460)

EXAMINING THE BINDING OF RADIONUCLIDES WITH MARINE BIOPOLYMERS, A COMPARATIVE STUDY ON TH, PA, BE, PO AND PB ISOTOPES

Both exopolymersic substances (EPS) from marine phytoplankton and natural colloidal macromolecular organic matter (COM) are able to strongly bind different natural radioisotopes that are used as geochemical tracers in marine systems, e.g., for POC flux dynamics and organic carbon cycling in the ocean, and aggregate. To study binding ability and aggregation propensity of different marine colloids and phytoplankton EPS, the chemical composition of radioactive metal-carrying biopolymers is currently being investigated to relate radionuclide binding to chemical composition of individual biomolecules. By separating and identifying radiotopic organic-carrier molecules, we found that the most efficient binding of many of these isotopes likely occurs to acid polysaccharide- and protein-containing biomolecules, i.e., proteoglycans, glycoproteins and sideropheric moieties. Furthermore, compared to silica particles and diatom frustules that were cleaned to selectively remove organic matter, particle-water partition coefficients (Kd) of selected radionuclides were greatly enhanced and showed high selectivity when diatom-associated organic matter was present. This suggests that chemical composition and types of organic functional groups are indeed crucial factors in the fractionation of all selected radionuclides in seawater. (Abstract ID 10365)

BIO-CONCENTRATION, BIO-MAGNIFICATION AND TROPHIC TRANSFER OF TRACE METALS OF MARINE ZOOPLANKTONS: ACTIVE OR PASSIVE

Bioactive trace elements (Cu, Ni, Cd, Zn and Fe) were taken up by phytoplankton in euphotic zone through various biological processes. As these elements came into the aquatic food chain, accumulated in the organism in the process of trophic transfer, any unassimilated trace elements are rapidly packaged into fecal pellets and transported out of surface waters. However, bio-concentration or trophic transfer of trace metals is caused by the dietary behavior or metabolic functions of zooplankton remain a main issue for biogeochemical cycle of trace metals in marine environment. Using ultradian size fraction techniques, elemental and metals concentration of selected zooplankton at various growth stages were analyzed. It was found, on average, that only ~75% of trace metals measured were intercellular. Mean concentrations of selected trace elements in zooplankton were increased with sizes, and the TM/Carbon ratio changed for different element of different rate at different growth stage. Fecal pellets, ecoskeleltons, and intracellular materials all show different metal concentration levels, degraded/released metal into the water columns at different rate. However, for Cd, concentration decreased with increasing sizes. These evidences suggest active accumulation of essential metals, not passively; and metal detoxification is actively involved in plankton life cycles which have profound impact on trace metals biogeochemistry in the ocean. THE OCEAN LITERACY PRINCIPLES—UNDERSTANDING THE IMPACT OF THIS EDUCATOR-SCIENTIST COLLABORATION ON PUBLIC UNDERSTANDING OF SCIENCE

This paper explores ongoing efforts to measure the impact of the Ocean Literacy Principles and the related materials that have resulted from educator-scientist collaborations led by the Center for Ocean Sciences Education Excellence—California (COSEE—CA). More specifically, COSEE—CA researchers have developed a survey that measures understanding and attitudes about the ocean and the role that ocean sciences play in supporting understanding of Earth systems by asking questions related to 4 dimensions: knowledge, attitudes, behaviors, and exposure. The instrument has been developed with the goal of yielding a tool that is easy to administer and analyze so that it will have maximum utility and flexibility. This measurement tool supports formative efforts (e.g. guiding the kinds of interventions used for targeted audience) and summative evaluation (e.g. measuring the impact of educational outreach efforts). This paper describes what we have learned to date through the developing and administering this instrument. It also discusses the potential uses for the instrument across the COSEE Network and beyond to measure impact of education and outreach efforts on the ocean literacy of target audiences. PROCESSES LEADING TO 210-PO AND 210-PB DISEQUILIBRUM ALONG THE GEOTRACES MERIDIONAL TRANSIENT OF THE WESTERN NORTH ATLANTIC

A western North Atlantic transect made in spring 2010 during GEOTRACES cruise GA02 that sampled 11 stations to 1000 m for the natural radionuclides 210Po/210Pb (granddaughter/parent) couple. A distinct 210Pb surface maximum in temperate subarctic waters corresponds to a maximum in excess 210Pb at depth. Auxiliary data show distinct productivity focused at the gyre boundary. This area is apparently deficient in Fe along the NADW subduction, deposition of Saharan dust is evident from auxiliary Fe and Al data. Here a CM/Carbon ratio changed for different element of different rate at different growth stage. One such hot spot is Bering Canyon in the southeastern Bering Sea, where the gyre boundary. This area is apparently deficient in Fe along the NADW subduction, deposition of Saharan dust is evident from auxiliary Fe and Al data. Here a CM/Carbon ratio changed for different element of different rate at different growth stage.

ADAPTIVE SAMPLING OF A BIOLOGICAL HOT SPOT IN THE BERING SEA USING AERIAL SURVEILLANCE

A biological hot spot in the ocean is a region with a high rate of energy transfer between trophic levels. One such hot spot is Bering Canyon in the southeastern Bering Sea, where strong tidal currents combined with a steep shelf break produce strong localized upwelling, and flow through the Aleutian passes bring productive Pacific Ocean water into the Bering Sea.
At top trophic levels, the energy transfer rate is not constant, but is concentrated in intense, ephemeral foraging events. This situation offers an ideal application for adaptive sampling using aerial surveillance to locate these foraging events and direct a surface vessel to obtain more detailed observations. In the example presented, three foraging events were located using an aircraft equipped with oceanographic lidar supplemental visual observations. A chartered commercial fishing vessel equipped with 38 kHz acoustics, and nets was directed toward one of these events where high concentrations of copepods, euphausiids, walleye pollock (Theragra chalcogramma), Pacific herring (Clupea pallasi), shearmovers (Procellaridae), and humpback whales (Megaptera novaeangliae) were documented. CHANGES IN THE TROPIC DYNAMICS OF THE WESTERN ENGLISH CHANNEL

Climate and anthropogenic changes can drive relevant changes in the dynamic of the trophic components of marine ecosystems, influencing their status and productivity. These changes can be investigated through the analysis of time series collected by long-term monitoring stations. In this work, we investigated the changes in the trend and relationships among the trophic components of the English Channel (UK), in relation to changes in climate forcings. Long-term time series of phytoplankton and upper trophic taxa sampled at the Western Channel Observatory were decomposed by using Dynamic Harmonic Regression (DHR) models, coupled with a Kalman filtering algorithm. The results show that changes in the physical forcings (e.g., sea surface temperature and wind intensity) impacted the community composition and the abundance of indicator taxa (e.g., calanoids). Correlation analysis among the long term components of the time series indicated changes in the trophic relationship between primary and secondary producers. This work points out that climate events can induce fast changes in the trophic relationships in marine food webs, with potential impacts on fish abundance. (Abstract ID 10038)

CLIMATE MIGRATION CHANGES PENGUIN DISTRIBUTIONS ON THE WEST ANTARCTIC PENINSULA

Rapid climate change in Antarctica appears to be altering the distribution and abundance of penguin breeding colonies. Adélie, Chinstrap and Gentoo penguins may differ in terms of their habitat use and distribution, and how their current habitat ranges may continue to be altered by future climate changes. Climate shift in more favorable conditions to the south, thus, illustrating where range expansion and contraction is occurring. Former ideal Adélie habitats are now becoming more suitable for Chinstrap and Gentoo penguins. These models may also describe uncolonized locations where range expansion and contraction is occurring. Former ideal Adélie habitats are now becoming more suitable for Chinstrap and Gentoo penguins. These models may also describe uncolonized locations where

CONTROLS ON PHYTOPLANKTON CELL SIZE DISTRIBUTIONS IN CONTRASTING PHYSICAL ENVIRONMENTS

Phytoplankton cell size is often thought of as a master trait, influencing both the trophic structure of marine ecosystems and important biogeochemical fluxes, such as carbon export from the photic zone. In phytoplankton, small cell sizes generally confer an advantage in terms of resource acquisition in low light and nutrient scarce environments, and the effective use of already-acquired resources. Large cell sizes can be advantageous in terms of avoiding predation, and for nutrient storage in variable environments. We investigate the relative importance of bottom-up and top-down controls on phytoplankton cell size in contrasting physical environments using an individual-based evolutionary ecosystem model (EVE), including a physiologically consistent model for sub-cellular resource allocation, size-dependent predation, and cell size as an evolvable trait. Coupled to the MIT OGCM, we use the model to derive dynamic optimal size-class distributions at representative 1-D sites, which are also compared with in situ data. Particular attention is given to both drivers for global patterns in phytoplankton cell size, and changes in the cell size distribution during phytoplankton bloom periods. (Abstract ID 11125)

A COMPARISON OF ON-SITE AND REMOTE EXPLORATION IN THE DEEP OCEAN

Deep-sea exploration is the very discovery of discovery in modern science. Plunging the depths of yet unexplored seafloor to investigate some of the most extreme and unique ecosystems is a challenge; however as it informative. However, this information is not easily accessible and the methods by which scientists investigate these habitats are evolving to meet this challenge. One such method being developed is remote communications technology that allows scientists to engage in exploration virtually from shore-based laboratories. As a doctoral student in marine ecology at Duke University, I have had unique opportunities using different technologies to participate in both exploration and research. Specifically, I have embarked on field expeditions aboard research vessels such as R/V Oceanus of the Woods Hole Oceanographic Institute and utilized state of the art satellite technology on a 'virtual cruise' with the NOAA Okeanos Explorer. In this poster presentation, I will discuss the scope and nature of deep-sea research, and compare and contrast the experiences between on-site oceanographic field research and the novel computerized 'virtual cruises' that are reshaping the accessibility of deep-ocean research. (Abstract ID 10482)

TOS/AGU/ASLO Abstract Book
Within the frame of the TARA expedition, we deployed a Bio-Argo float in the Marquesas plume to investigate the productivity of this “green spot” within the blue sub-equatorial Pacific waters. The float measured temperature, salinity, irradiance at three wavelengths, the backscattering (bbp) and attenuation (cp) coefficients as well as Chls and CDOM fluorescence. It was operated three times per day (sunrise, noon, sunset) every day for an initial period of 55 days and every five days thereafter. We present here the analysis of this highly resolved time series. From the diel cycle in bbp (converted into POC) and Chla we estimate rates of Gross Community Production. We show that these rates are linked to the thickness of the mixed layer suggesting a control by available radiation. The absence of a diel cycle in bbp suggests this quantity is essentially driven by the presence of non-living (detritus or suspended sediments) material. Finally the spatial and temporal dynamics of “erratic spikes” in the cp and Chla vertical profiles is analyzed with respect to export dynamics of the locally produced material. (Abstract ID 10245)

A FRENCH OUTFREACH INITIATIVE INCLUDING OCEANOGRAPHIC AUTONOMOUS OBSERVATIONS

The OAO (Oceanographic Autonomous Observations) team operates automatic platforms such as gliders and profiling floats and is also strongly implicated in the technological development of their “new generation” in terms of scientific payloads. The acquired multi-sensor data, particularly focusing on marine biogeochemically-relevant data (e.g., oxygen, nitrate, chlorophyll-a, amount of light penetrating the Ocean) together with temperature and salinity, then serve within the wide fields of fundamental research and operational applications. Within this framework and making use of the exceptional characteristics of such autonomous platforms (e.g., multidisciplinary real-time data in high resolution, possibility for sub-regional to global perspectives), the OAO team also seeks to contribute the more and more towards educational and outreach activities. On a local, national and international basis, thus several activities are proposed and the development of attractive outreach approaches is undertaken (e.g. facilitator program). Aiming to broadly capture an interest in Ocean Sciences and to initiate or deepen the understanding of the Oceans and their functioning, these initiatives are meant as complementary actions with an integrative and whenever possible collaborative intention to efforts of existing and emerging networks. WAVE EFFECTS AND STABLE BOUNDARY LAYERS ON AIR-SEA FLUXES

Many internal turbulence aspects of the ocean boundary layer can affect the sea surface temperature, thereby influencing the fluxes of latent heat, sensible heat, and upwelling long wave radiation. In this work we focus on the effects of turbulence created by wave breaking and Langmuir circulations on the sea surface temperature, and on the effects of a strongly stable ocean boundary layer. These varying aspects of the upper ocean are studied singly and in concert through the use of a second moment closure model that models the enhancement of turbulence kinetic energy from both wave breaking and Langmuir circulations. The effect on the surface fluxes of these variations in sea surface temperatures are shown for a range of conditions that are appropriate to the regimes in which they are occurring. THE KURISHIO FRONT: ECOLOGICAL BARRIER OR BLENDER?

We performed a fine-scale survey of phytoplankton communities across the Kuroshio Extension in the North Pacific to examine the role of cross- and along-frontal dynamics in regulating the local community structure and diversity. Western Boundary Current fronts are the interface between subtropical and subpolar gyres supporting swift, along-frontal currents separating the waters of the gyres and their associated plankton populations. A cluster analysis of the observed pico- and micro-phytoplankton distributions reveals a sharp divide between clearly distinct phytoplankton communities either side of the front, suggesting an ecological barrier. However, a targeted molecular study of Ostreococcus shows that coastal and oceanic clades of this picophytoplankton genus co-occur at the front. We observe a slug of coastal water entrained into the stream, at the edges of which we see evidence of fine-scale mixing of the two Ostreococcus clades. Western Boundary Current fronts appear to be acting as both ecological barrier and blender, depending on the temporal and spatial scales of interest. (Abstract ID 9517)

MULTIPLE TRACER CONSTRAINTS ON THE ANTHROPOGENIC CO2 UPTAKE BY THE OCEAN

Transient tracers such as CFCs and C-14 provide valuable information on the oceanic uptake of anthropogenic CO2. In a model framework, we examine the relationships between anthropogenic CO2 and the two tracers CFC-11 and C-14 on inventories computed over either isopycnal slabs or vertical columns. Due to different solubility characteristics, concentrations are normalized by accounting for the effects of CFC solubility and the Revelle factor, respectively. We find linear relationships on a basin-scale in the ETH runs of the NCAR CCSM-ocean model, that have proven to be robust by conducting the same analysis with simulation output of the Ocean Carbon Model Intercomparison Project (OCMIP). With new datasets from international synthesis programs having become available recently, we will apply these relationships to observational tracer data to estimate both the global anthropogenic CO2 inventory for the mid-1990 and the decadal change since that time. These results will be compared to the estimates from several other methods (ACT, TTD, eMLR, etc.). As a rather direct approach, with its distinct strength and weaknesses, it will serve as an additional independent constraint on the anthropogenic CO2 uptake by the ocean. (Abstract ID 11906)

On the vertical structure of westward propagating anomalies in the north atlantic and their impact on the moc at 26.5’n from observations.

The Meridional Overturning Circulation (MOC) measured at 26.5°N in the North Atlantic exhibits a mean transport of 17.9 Sv and a standard deviation of 4.7 Sv from April 2004 to December 2010. The subannual variability of the geostrophic transport is believed to be partly caused by Rossby waves and eddies (Hirschi et al., 2007). This hypothesis is tested by studying westward propagating anomalies along the RAPID moorings, which may impact the western boundary dynamic height profile through isopycnal displacements. The characteristics (period and wavelength) of these anomalies are compared to the theoretical dispersion relation and observations of planetary waves from altimetry. Their vertical structure is evaluated at each mooring of varying longitudes through normal mode decomposition. Rossby wave propagation is estimated using coherence between modal amplitudes at different moorings. (Abstract ID 9466)

SIMS ANALYSIS OF PRIMARY AND INFILLED AREAS WITHIN STYLASTER ERIBESCENS COLONIES

Hydrocorals, such as Stylaster eribescens, contain infilled canals and pores of secondary aragonite which may complicate their use as geochemical climate proxies. The small size (often <0.5 μm) of the infilled areas makes comparison of oxygen isotope values between primary and secondary skeleton difficult. Sections of Stylaster eribescens collected at the Charleston Bump (400-600m depth North Atlantic, NW Blake Plateau) were cast in 1 inch epoxy mounts, ground, and polished. Imaging via SEM was used to identify and characterize infilled areas. 8°O analysis was performed in situ from 1.2 micron spots using SIMS to directly compare the 8°O values of adjacent primary and secondary skeletal areas. Results show that infilled areas do contain 8°O values that differ from that of the surrounding primary skeleton. This will complicate the use of S. eribescens as geochemical climate proxies. OPTICS AND COMPOSITION OF PARTICULATE MATTER IN HYPOXIC AREAS OF THE TEXAS/Louisiana SHELF

Particulate matter in hypoxic areas of the TVLA shelf have three major sources – river plumes, primary production, and resuspended sediments. The sources and processes controlling distribution and transport of these particles can be investigated through optical and in-situ sampling and analysis. Discrete samples for particulate matter (PM) and particulate organic carbon (POC) concentration were filtered for calibration of optical measurements interfaced with the CTD and flow-through systems during the June and August 2011 cruises of the Mechanisms Controlling Hypoxia program, which began measuring T, S, Oxygen, beam attenuation, Fl and PAR annually in 2004. Continuous measurements of surface beam attenuation and CDOM fluorescence (Wet Labs) plus T, S and Fl were made during 2011 using the ship's flow-through system along the entire cruise track from south of Galveston, Texas to east of the Mississippi outflow. Concentrations, gradients and ratios of optical and compositional values are being used to infer sources of particles and their relationship to, and influence on, areas of hypoxia. RELATING TIDAL CYCLES OF STRATIFICATION, SHEAR, AND TURBULENCE TO ESTUARINE RESIDUAL FLOW

Tidal variability in estuaries commonly exceeds non-tidal residuals, yet is omitted from traditionally derived tidal-average momentum dynamics. Tidal correlation (TC) terms occur at lowest order and could cause substantial changes to the dynamics, strength, and even sense of residual flow. Relative phasing of tidal cycles in stratification, shear, and turbulence vary dramatically in space and time. Relative phasing control over TC terms and associated residual flow is examined using analytical models and an observational case study of Eastern Long Island Sound (LIS) near the estuary axis (moored CTD profiler records for stratification, and turbulent overturns using Thorpe-sorting and a ferry-mounted ADCP). Sensitivity to relative phases in the analytical model is underscored by the case study. In LIS near the bottom, stratification varies weakly and peak shear during flood apparently dominates turbulence characteristics. By contrast, in the upper water column tidal strain is active, with shear, stratification, and turbulent overturns all peaking during late ebb and slack after ebb; low Richardson numbers indicate shear drives enhanced turbulence during peak stratification, unlike in other systems where turbulence is suppressed by stronger ebb stratification. ATMOSPHERIC CIRCULATIONS INDUCED BY A MID-LATITUDE SST FRONT: A GCM STUDY

The LMDZ AGCM is used with a resolution locally enhanced to 0.5° to analyze the impact of a sharp SST front in the North Atlantic: two perpetual-winter simulations are compared, one with climatological high-resolution SSTs, the other with an enhanced Gulf Stream front. The results corroborate the theory developed previously by the present team to explain the impact of oceanic fronts: the vertical velocity at the top of the atmospheric boundary layer has two components: mechanical (driven by the free-atmosphere vorticity) and thermal (driven by the Laplacian of the boundary-layer temperature). The latter is dominant in the tropics, while in mid-latitudes both play a role in determining the boundary-layer wind convergence. The strengthened SST front does generate the predicted stronger ascent above the warmer waters south of the front and stronger descent above the colder waters to the north. The simulated ascent over the warm anomalies is deeper and more intense than the descent and is accompanied by enhanced precipitation. The vertical shear of the along-front velocity is also modified by the stronger front, as is the cloudiness structure. (Abstract ID 12011)

PLUME SIMULATIONS USING OCEAN MODEL ENSEMBLES FOR THE FUKUSHIMA DAI-ICHI NUCLEAR POWER PLANT ACCIDENT

The Fukushima plant damage caused radioactive contamination of coastal waters. Major issues characterizing the extent of the affected waters were a poor knowledge of amounts released and the complex coastal dynamics of the region that are not deterministically captured by the prediction systems. To assess the areas that were most likely affected by the accident, while taking into account these limitations and uncertainty in model velocities, an ensemble of 32 runs of the Navy Coastal Ocean Model was configured over the region. Tracer particles have been released on each ensemble member, every hour since the accident time; their locations at each instant can be considered as mean positions of reference water volumes or radioactive amounts, and used to identify areas where signatures of water released from the plant could be found. Results were then compared and integrated with a direct diffusion-advection solution based on the available reports defining inputs of radiation over the coastal region. A stochastic plume was then determined using Risk Assessment Code analysis that associates a number from 1 to 5 to each grid point, determined by the likelihood of having an high radiation concentration and/or tracer particle within short ranges, hence defining high risk areas and those recommended for monitoring. Maps detailing the risk assessment will be discussed using available local observations to assess their consistency and relevance for planning surveys and oil recovery operations at sea. (Abstract ID 10570)

POLEWARD THERMOHALINE CIRCULATION ON THE SOUTHEAST BERING SEA SHELF

To understand future effects of climate variation in the SE Bering Sea, we need to understand the response to present conditions. Previous investigations of the continental shelf have included closely spaced hydrographic (CTD) casts, but along isolated sections that were too far apart to draw detailed inferences about water properties and flow between sections. We present measurements from 3 summers (2008-2010) on a 37x37-km spaced grid of approximately 300 CTD casts covering most of the shelf during NOAA's bottom trawl surveys. This gives the first comprehensive 3-D view of the temperature, salinity and density fields including the
multi-layered nature and ecologically important Cold Pool (temperature < 2°C). Geostrophic velocity vectors from the gridded observations reveal the thermohaline circulation. Results from all 3 years show consistent poleward flow of warm water along the outer temperature front (above the 100-m isobath) from the Pribilof Islands, across the shelf, past St. Matthew Island and into Russian waters. Satellite-tracked drifter trajectories confirm this circulation. The observations come from 3 “cold” years; inferences about climate change await future “warm” year measurements. (Abstract ID 10574)

THE AZORES MARINE PARK: DEEP-SEA FEATURES AND MULTI-PURPOSE MARINE PROTECTED AREAS

Portugal with its archipelagos has one of the largest European EEZ’s and expects to obtain jurisdiction over a major North Atlantic seabed area in case its extended continental shelf claim is accepted at the UN. Most of this seafloor corresponds to a diversity of deep-sea habitats. The promising economic opportunities of mineral resources, bioprospection for pharmaceutical and industrial applications increases the responsibility to the nation’s stakeholders. Based on OSPAR and IUCN Guidelines for the Management of MPAs, plans for deep-sea MPAs where produced for the vent fields Lucky Strike and Menez Gwen hydrothermal; and Dorn João de Castro and Sédio seamounts. In view of the extended shelf claim, the Azores Regional Government will be responsible for four additional deep-sea protected areas; Rainbow vent field, the Mid-Atlantic Ridge (box) North of Azores, the Altair and Antaimaur seamounts. In response to the multiple designs and management requirements of areas between the 12nm territorial sea limit (the EEZ) and the extended shelf claim boundary, the Azores Government created the Azores Marine Park. The process leading to its legal creation is reviewed and discussed. (Abstract ID 11699)

INTERANNUAL VARIABILITY IN GLOBAL PHYTOPLANKTON PHENOLOGY

Large areas of the world’s oceans experience a significant seasonal cycle in phytoplankton biomass. The timing of the bloom affects ecosystem dynamics with implications for biogeochemical cycles and higher trophic levels. Phenological changes may additionally indicate climate change, as the physical processes that control timing alter in a warming world. However, to understand future phenological changes we must first determine variability in timing and what drives it. Here, phytoplankton phenology metrics such as bloom initiation and peak are calculated globally using satellite ocean colour data. The impact of gaps in the time-series is investigated using a global biogeochemical model that assimilates SeaWIFS data. We find that the missing data significantly alter estimations of bloom timing. This uncertainty is seen to vary spatially and between different methods of calculating the same metric. We choose the most reliable metric based on this analysis to explore the relationships between interannual variability in phenology and underlying physical drivers, such as mixed layer depth and climate oscillation indices. Relating phenology to indicators of ocean variability offers new insights on the mechanisms that control bloom dynamics. (Abstract ID 10187)

Ice-ocean interactions on inertial to monthly timescales are studied using winter 2009-2010 observations from the first ice-Tethered Profiler equipped with a velocity sensor. Ocean velocity spiraled clockwise and decayed with depth through the surface mixed layer. Directly-estimated turbulent momentum flux just below the ice-ocean interface was correlated with the ice-ocean velocity difference, allowing a drag coefficient to be estimated. The ice-ocean drag coefficient had larger values derived for straight ice-drift segments and certain ice-drift directions. The surface-layer turbulent kinetic energy dissipation rate also scaled with ice-ocean velocity shear. Inertial or tidal energy in the ice velocity and internal wave fields was observed throughout the record with elevated energy associated with increased stratification within the surface layer and a slightly thicker surface layer. The direct turbulent heat flux was primarily upward, and the direct turbulent salt flux had alternating sign due to brine rejection during ice formation and internal wave mixing and entrainment. Analyses of this and future ITPV data sets will advance understanding of ice-ocean interactions and their parameterizations in numerical models. (Abstract ID 10246)

REMOTE OBSERVATIONAL OCEANOGRAPHY USING SHIPS OF EXPLORATION AND SATELLITE/INTERNET TELEPRESENCE SYSTEMS

Telescope technologies combined with high-bandwidth video/data streaming and online portals will bring vast quantities of information about the remote oceans to interested people worldwide. During the next 20 years, these technologies will empower scientists and educators to become deeply involved in observational oceanography in real time, facilitating the decision-making process and remote control of and interactivity with sensing systems and instrumentation on remote platforms. The Inner Space Center (ISC) at the University of Rhode Island Graduate School of Oceanography works directly with two ships of exploration, the NOAA Ship Okeanos Explorer and the R/V Nautilus. During the 2010 and 2011 field seasons, the ISC helped support multiple expeditions onboard these platforms by enabling teams of scientists, students, and educators to take part in the field program remotely, providing access to video and data streams and facilitating remote ship-to-shore telecommunications. These capabilities have been tested and protocols have been refined for remote operations with high success, but with expected operational and technological challenges associated with this new paradigm. By 2030 we expect this new paradigm to be established and mainstreamed on many remote ocean observing and exploration systems. (Abstract ID 12791)

EXPLORING INNER SPACE – EDUCATIONAL KIOSKS AND COMMAND STATIONS FOR INTERACTING WITH OCEAN EXPLORATION CONTENT IN AQUARIUM SETTINGS

Through a partnership between the NOAA Office of Ocean Exploration and Research, the University of Rhode Island Inner Space Center (ISC) at the Graduate School of Oceanography, COSEE, and the Mystic Aquarium and South Carolina Aquarium, we have developed a proof-of-concept interactive system for engaging public audiences with ocean exploration content. Modeled after remote scientific exploration command consoles, the ISKiosk and command station enables aquarium visitors to connect with exciting programs in ocean exploration led by marine scientists. The scientists involved in the exploration programs are excellent resources to help develop and produce the educational content that will aim to improve ocean literacy. This program will expand and grow as more aquariums, science centers, and other
informal education facilities become equipped with the technologies to connect with the ISC. Opportunities exist for ocean scientists engaged in seagoing exploration to communicate their work through this program. (Abstract ID 12802)

THE ROLE OF THE AMAZON RIVER PLUME IN STRUCTURING UPPER OCEAN STRATIFICATION, BIOCHEMISTRY, AND BIOLOGICAL COMMUNITIES IN THE WESTERN TROPICAL NORTH ATLANTIC

The Amazon River discharges into the equatorial Atlantic Ocean, forming a surface fresh plume layer that extends more than 2000km from the river mouth. Results from two cruises (spring 2010 and fall 2011) undertaken as part of the multidisciplinary ANACONDAS field campaign illustrate the dynamic nature of the plume and its role in modifying the upper ocean currents. Velocity fields show distinct vertical shear associated with the salinity stratification. Stair-step salinity structures sometimes occur beneath the prism plume layer. These may indicate fossil (older) plume water and they often harbor unique biochemical signatures and communities. Vertical salinity fronts with strong surface expression and suggestion of vertical velocities were observed in a semi-permanent eddy in the North Brazil Current retroreflection in fall. The fronts have a visual colored dissolved organic matter signature, and also tend to damp surface gravity waves and whiteness expression on the plume side, suggesting that salinity barrier layers may reduce air-sea exchange of dissolved gases. EFFECTS OF FORAGING MODE AND TURBULENCE ON THE ENCOUNTER RATES OF THE LORATE CTENOPHORE ANOMENIOPSIS LEDYI

The lobate ctenophore, Anomniopsis leidy, is a voracious zooplankton predator which generates a laminar feeding current to encounter prey (i.e.; suspension foraging). However, it has been suggested that encounters with faster swimming prey, such as copepods, are primarily initiated by the prey inadvertently swimming into the ctenophore (i.e.; ambush foraging). Since the effects of turbulence vary depending on foraging mode it is important to understand how encounters are initiated for different types of prey. We used a simple empirical model to get a first order approximation of how foraging mode affects the encounter rates of A. leidy with prey. Further, we examined how different levels of turbulence may alter encounter rates. The importance of copepod initiated encounters varied for different copepod sizes and corresponding swimming speed. However, for copepods such as Centropages hamatus encounters initiated by the copepod were much greater than those by the feeding current. As expected, the relevance of turbulence varied depending on the encounter mechanism. Model results were compared to preliminary observations of encounters with prey. (Abstract ID 9963)

LATERAL ADVECTION OF MOMENTUM AT THE SHOAL-CHANNEL INTERFACE IN A PARTIALLY-STRATIFIED ESTUARY

The contribution of non-linear advection terms to the tidally-averaged longitudinal momentum budget in a partially-stratified estuary has traditionally been assumed small compared to the tidally-averaged longitudinal baroclinic pressure gradient and vertical Reynolds stress divergence. However, recent studies have found non-linear advection terms contributing at leading order in various cases, therefore questioning the skills of traditional scalings of the estuarine circulation. In this talk we examine the lateral advection of momentum at the shoal-channel interface of a partially-stratified estuary using transect observations and data from moored instruments distributed across the interface in South San Francisco Bay. We find that lateral advection of momentum in the channel is strongest late in the ebb, when the lateral shear is the strongest and densest water from the shoal plunges down the slope toward the channel. As a result, the tidally-averaged lateral advection term acts to increase the residual circulation, favoring inflow at the bottom and outflow at the surface. Comparison with ADCP measurements of the tidally-averaged vertical Reynolds stress divergence also suggest that lateral advection contributes at leading order in this system. (Abstract ID 9989)

IN SITU MEASUREMENTS OF SURFACE GRAVITY WAVES IN TYPHOON CONDITIONS

Wave data from four buoys is presented from the recent Impact of Typhoons on the Ocean in the Pacific (ITOP) experiment. Two Air-Sea Interaction Spar (AISI) buoys and two Extreme Air-Sea Interaction (EASI) buoys were moored in “Typhoon Alley” off coast of Taiwan for four months. The buoys measured waves from 4 tropical cyclones in which significant wave heights in excess of 10 meters were recorded. Preliminary findings using Heave-Pitch-Roll (HPR) analysis on the EASI buoys (Nomad type hull) shows promise for uncovering directional information. Comparisons/validations are performed among the 4 moored buoys as well as with drifting Minicat Wave Buoys, marine radar (WamM II), and altimeter satellite (JASON). (Abstract ID 10430)

HMA: A META-DATABASE FOR GENOMES, METAGENOMES, AND PHENOTYPES FROM COLD ENVIRONMENTS

The recent flood of sequencing data has been a boon for the traditionally data-poor discipline of biology, but can also prove overwhelming. For microbial ecologists, it would be useful to access a database of phenotypic traits for cultured species of microorganisms, but there does not yet exist a comprehensive database linking genome, taxonomy, and phenotype from environmental isolates; neither are detailed metadata always submitted by sequencing facilities and investigators. For example, no queryable database exists to get a list of all known strains of Bacteria that reduce sulfate, or strains which grow at temperatures below 10°C. As an initial foray into a web-based database linking phenotype and genotype, I have created a database linking sequences and phenotypic data (which are often archived in disparate locations and formats) of cold-active microorganisms from all three Domains of Life. When available, I include sampling environment, location, temperature and growth range, depth, sequencing platform, amount of data, etc. Currently, the database includes 50 complete genomes sequences as well as 444 metagenomes, including a number of transcriptomes and viromes. Isolates and environmental samples, collected between 79°N and 77°S, come from many environments. The database—called “hima” after the Sanskrit word for snow or cold—will be updated into the future and further expanded to include analytical resources; it can be accessed at http://veric.org/work/hima/. (Abstract ID 12871)

OBSERVATIONAL EVIDENCE OF AN INCREASE IN VERTICAL MIXING SOUTH OF THE POLAR FRONT IN THE SOUTHERN OCEAN USING OBSERVATIONS OF RADIIOCARBON AND SURFACE CO2.

Measurements of surface water pCO2 and 14C/12C of dissolved inorganic carbon (C-14) south of the polar front suggest that estimated increases in Southern Ocean winds may be driving an increase in vertical mixing of deep waters to the surface which has acted to decrease the Southern Ocean sink. The increase in vertical mixing is demonstrated by a (70±14 %) decrease in C-14 between 1973 and 2006 in the Drake Passage south of the Polar Front and a steeper meridional gradient of surface water C-14 across the polar front. Using a GC model we estimate that ~75% of the observed decrease in surface C-14 is due to the large decrease in atmospheric 14C/12C as result of nuclear bomb testing. The decrease in C-14 is synonymous with an increase in surface water CO2 south of the polar front region of the Southern Ocean which is significantly greater than that expected from the rise in atmospheric CO2 observed over the last 30 years. These observations are significant because they support the low resolution GCMs which show a decrease in CO2 uptake in the Southern Ocean due to upwelling of carbon rich deep waters south of the Polar Front. The potential biases of these data based estimates will be discussed. (Abstract ID 12385)

MODELING THE OXYGEN ISOTOPE COMPOSITION OF PHOSPHATE IN AQUATIC ECOSYSTEMS

The oxygen isotope composition of phosphate (δ18Op) has emerged as an important tool for understanding rates and mechanisms of phosphate uptake and regeneration in the oceans. Microbial phosphate cycling leads to the rapid exchange of phosphate oxygen with water oxygen. Early culturing experiments suggested that phosphate remineralization would result in δ18Op values consistent with isotopic equilibrium. Indeed, measurements of δ18Op in the coastal ocean and deep ocean have indicated that phosphate cycling often leads to isotopic compositions near equilibrium. However, a wide range of experiments on a variety of phosphoprophylase enzymes suggest that remineralization can easily lead to large excursions from isotopic equilibrium. Here we assemble a generalized model that highlights the potential importance of pyrophosphatase and cell lysis for exerting significant control over δ18Op. We show how these results can inform our understanding of couplings between P and C cycles in the euphotic zone of a continental margin environment, the euphotic zone for open ocean oligotrophic environments, and the deep ocean. MEAN AND SEASONAL TRANSPORT VARIABILITY IN THE SOUTHWEST ATLANTIC DERIVED FROM A TWO-WAY NESTING MODEL EXPERIMENT

The Southwest Atlantic Circulation (SWAC) is principally governed by the interaction of the Brazil Current and the Malvinas Current originating from the Antarctic Circumpolar Current (ACC). Previous studies have shown a deficiency in reproducing an acceptable position of the Brazil/Malvinas confluence, noticeable in coarse-resolution models. Facing the dilemma between the need to have a high-resolution model grid applied to the SWAC region and to resolve the large-scale ACC, our study uses ROMS ocean model at a 1/12°x1/12° resolution for the SWAC region embedded into a coarser-resolution (1/4°x1/4°) southern hemisphere grid. We find a strong agreement between the modeled and observed latitudinal position of the confluence at ~39°S. We present evidences that during austral summer (winter), the southward (northward) displacement of the confluence coincides with an intensification (weakening) of the Brazil Current, which is found to respond to a strengthening (weakening) of the wind stress curl in the SWAC below ~3°S. This study also highlights the asymmetry between Brazil and Malvinas currents transports, with a weakening of the Malvinas current during summer. Those hypotheses are supported by a passive tracer method. (Abstract ID 9622)

OCEANIC TRANSPORT AND ITS ROLE ON THE SNOW BALL EARTH HYPOTHESIS

Balance models have been proposed to model the dynamics of the Earth’s climate at long time scales, primarily to discern the role played by changes in the Sun’s input on geologically-documented periods of climate change. Previous models capture the radiative balance, radiation changes, and the albedo effect. More recent models also include a dynamic for the ice sheets. We investigate the role played by oceanic transport on a balance model by coupling the ice sheet thermodynamics, radiation effects, changes in solar radiation, and the flow of a zonally-averaged ocean. We use this model to determine the importance and manner in which oceanic transport affects ice sheet coverage at climatic scales, as well as how ice melting and freezing affects the classic thermaline scenario for ocean overturning. IS CALCIIFICATION IN THE SCLERACTINIAN CORAL PORITES RUS AND THE CRUSTOSE CORALLINE ALGA HYDROLITHON ONKODES CONTROLLED BY BICARBONATE OR CARBONATE IONS?

In the context of contemporary ocean acidification (OA), it is critically important to understand the mechanism(s) of calcification on tropical coral reefs, and how it responds to declining carbonate ion concentration ([CO3]2-). In order to evaluate the roles of [CO3]2- versus bicarbonate ion concentration ([HCO3]-), Porites rus and Hydrolithon onkodes were maintained for 2 weeks under a matrix of 9 treatments representing three [CO3]2- crossed with three [HCO3]-. Both [CO3]2- and [HCO3]- played a significant role in light and dark calcification of P. rus, whereas [HCO3]- mainly affected calcification in the light. Both [CO3]2- and [HCO3]- had a significant effect on the calcification of H. onkodes, but the strongest relationship was found with [CO3]2-. Therefore, calcification of both P. rus and H. onkodes appears to be dependent on more than one species of the DIC system, and is affected by the availability of both [CO3]2- and [HCO3]-. These results suggest that the decrease in [CO3]2- expected as a result of OA, and its associated effects on coral reef calcification, might then be mitigated by the ability to also use HCO3- to calcify. The complete 1979-1986 and 1997-2010 NASA climatology, yearly and seasonal Level-3 Standard chlorophyll map sets were analysed using principal component analysis. The first component identifies the characteristic chlorophyll structure for the period under study, whereas the second outlines the major differences between the original maps. Higher components permit the identification of spatially and temporally local variations and anomalies. Water masses having seasonal averaged chlorophyll values up to 0.8 mg m-3 present a cyclic variation showing highest chlorophyll concentrations during the winter months and lowest values during summer months and the basin or the sensor under consideration. The Gulf of Mexico was temporally and spatially the most dynamic of the three basins under study. (Abstract ID 10349)

HYDROCARBONS AS SUBSIDY ENERGY FOR MICROBIAL AND FOOD WEB PRODUCTION IN COASTAL GULF OF MEXICO WATERS

Deepwater Horizon was unprecedented in total loading of petroleum hydrocarbons and chemical dispersants released into a marine environment. To better understand source-sink dynamics of oil-derived carbon and surface spill impacts on microbial food web processes, we conducted mesocosm experiments, and field surveys under pre- and post-spill conditions, measuring a full suite of chemical and microbial metabolic parameters. 13C was used as a tracer of oil to resolve isotopic carbon depletion in dissolved inorganic pools. High initial spikes in microbial growth were observed in oil only treatments but cell numbers declined rapidly after 24h. Sustained, high-level production was also observed in dispersed oil treatments but growth was delayed by 48h. In the field, localized spikes but greatly reduced seasonal dissolved organic carbon, increased offshore microbial production, and carbon depletion were coincident with surface oil slicks, and demonstrated oil carbon was respired. In addition, total chlorophyll-a remained low compared to pre-spill years, and contained 100 times less carbon than surface oil. Collectively, these results suggest increased influence of the ‘microbial loop’ under oiled conditions with implications for trophic dynamics in the Gulf. (Abstract ID 11552)

HYPOXIA IN A HISTORICAL PERSPECTIVE – INDICATORS OF CHANGE

The spatial extent and severity of hypoxia in the Baltic Sea is believed to have increased over the last century with discharges of nutrients, although there are few quantitative studies. Monitoring of oxygen beginning in ca. 1900 suggest that hypoxia was confined to the very deep parts of the Baltic, but the scarcity and heterogeneity of the data (in both vertical and horizontal space) complicate the assessment of hypoxic area and volume before ca. 1970 and confident analysis of non-climatological chlorophyll data based on the World Ocean Database.

The historical archives of in situ chlorophyll data from the National Oceanographic Data Center were used to analyze long-term patterns in the non-climatological distribution of chlorophyll at regional scales. We will show the distribution of “outliers” from mean climatological chlorophyll fields and analysis of patterns and trends at various regional and temporal scales. These analyses contribute to our understanding of climate variability and climate change impacts on marine ecosystems. The historical archives at the National Oceanographic Data Center (NODC) preserve historical ocean observations dating back to the early 1700’s to the present. These data have been used to create the much cited World Ocean Database and World Ocean Atlas (WOA) series of atlases of key ocean variables. We used the latest update of WOD and WOA for this analysis. This analysis continues the long history of NODC to provide baseline information for key variables and examine the deviations from the baseline. (Abstract ID 11164)

ANALYSIS OF NON-CLIMATOLOGICAL CHLOROPHYLL DATA BASED ON THE WORLD OCEAN DATABASE

In a recent field investigation of the interactions between sediment and turbulence, three separate sensors used to collect information on suspended sediment load were co-located in the neashore. These included a multi-frequency acoustic backscatter sensor (ABS), a fiber optic backscatter sensor (FOBS) and a digital holographic camera. Each sensor has its own strengths with the FOBS nominally providing high frequency concentration measurements up to the water surface, the ABS providing multi-frequency responses with the potential for grain size estimation; and the holographic camera providing direct information on the sizes and shape and distribution of the local suspended sediment load as well as permitting segregation of the suspended material into sediments, organic matter and bubbles. Initial results indicate general consistency between the sensors on a mean basis but with clear instances of significant disagreement. We shall analyze the results to perform a cross-comparison of the sensors, examine the relationship between imdered size differentiation capabilities of the multi-frequency ABS sensor; and seek to determine the relationship between the size-distribution of the bed material and the suspended load. Assessing data collection, spatial and temporal patterns in crowd source bathymetric data

Crowd Source Bathymetry (CSB) data may be collected by any type of vessels, a variety of sonar
systems, and for myriad reasons. Enlisting the resources of recreational boaters, pilot boats,
tug boats, cruise ships, as well as fully equipped survey ships in the “opportunistic” acquisition
of bathymetric data may potentially open data streams of current observations to navigators,
cartographers, scientists, and engineers. Using autonomously collected time, observation, and
position data from test vessels that operated without regard to bathymetric survey objectives,
we characterize the statistical representation of seafloor structure from these sources and
derive comparative differences with existing survey data. Potential types of data streams are
envisioned and simulated for comparative purposes. One strength of CSB data is the temporal
frequency in repeat observations, while spatial representation is less evenly distributed.

Ocean acidification, caused by increasing pCO2

Ocean Drilling Program (IODP) drillship JOIDES Resolution. In an effort to educate, inspire and

Public - these educators use the authentic, cutting-edge research being conducted on the ship

LIVE FROM THE OCEAN: AN OVERVIEW OF RECENT EXPERIENCES

Deep Earth Academy calls Onboard Education Officers on every expedition of the Integrated
Ocean Drilling Program (IODP) drillship JOIDES Resolution. In an effort to educate, inspire and
excite a wide variety of audiences — including teachers, students of all ages, and the museum-going
public — these educators use the authentic, cutting-edge research being conducted on the ship,

TOS/AGU/ASLO 2012 Ocean Sciences Meeting
to engage these audiences through live ship-to-shore video broadcasts, blog posts, photos and videos, related classroom activities, and social networking sites such as Facebook and Twitter. Over the course of more than three years, the technology and methodology used has evolved, as have best practices, feedback mechanisms, and support for educators and their participants. This session will share these lessons learned, statistics and feedback, and explore questions for achieving broader reach going forward. (Abstract ID 11149)

ADRIATIC SEA DECISION SUPPORT SYSTEM (ADRI-DSS)
The Adriatic Sea Decision Support System (ADRI-DSS) consists of an on-line service built upon a set of integrated operational oceanography products. ADRI-DSS integrates the Adriatic Sea forecasting system (AES) products with coastal in-situ observations from the Regional Environment Protection Agency (ARPA-EMR) of Emilia-Romagna (Italy) to support ARPA-EMR activities of coastal monitoring. Specifically ADRI-DSS supports the daily action of ARPA-EMR integrating and providing different types of operational oceanography products (forecast, observations, simulations). ADRI-DSS integrates with the routinely observations that the user carry out on a weekly basis. The system has been designed through the interaction with ARPA-DAFNE and consists of an online portal containing simulation and forecast for the relevant north Adriatic region. Moreover the models products are compared with in-situ observations of temperature and salinity collected by the ARPA-DAFNE itself and different types of online data post-processing are available for the user. The final aim of ADRI-DSS is to integrate selected products from the AES with the in-situ observations to support the monitoring and marine environment status assessments of ARPA-DAFNE. ISOLATION OF BLACK CARBON FROM MARINE DISSOLVED ORGANIC CARBON USING A REVISED SOLID PHASE EXTRACTION METHOD
The presence of black carbon (BC) in marine dissolved organic carbon (DOC) may be a key to understanding the old 14C age of DOC. Measurements of BC in DOC have been constrained by the ability to obtain representative samples of the bulk DOC pool itself, including both the high and low molecular weight fractions in which char and soot BC are present. Previous work by Ziolkowski and Druffel (2009) reported a low abundance of BC in the high molecular weight (HMW) DOC fraction. However, the HMW-DOC in their study represents only one fourth of the bulk DOC pool. Here, we report progress on a modification of a Solid Phase Extraction method (de Jesus, 2008) to extract bulk DOC. We then subject this extracted organic matter to acid hydrolysis using the Benzmere Polycarboxylic Acid method and isolate the derivatized BC markers using preparative capillary GC. With this method development, we have the ability to quantify and measure the 14C/12C ratio of BC in the bulk DOC pool to better understand BC cycling in the ocean and its possible importance as a carbon sink in the ocean. De Jesus, Roman (2008), Natural abundance radiocarbon studies of dissolved organic carbon (DOC) in the marine environment. Doctoral Thesis, U.C. San Diego, pp. 83 Ziolkowski, L. A., and E. R. M. Druffel (2009) reported a low abundance of BC in the bulk DOC pool to better understand BC cycling in the ocean and its possible importance as a carbon sink in the ocean. (Abstract ID 9696)

AN INVESTIGATION OF SPATIAL AND TEMPORAL VARIABILITY OF SURFACE SEABED PROPERTIES AND ERODIBILITY ON THE WAIPAOA RIVER MARGIN, NEW ZEALAND
Margins with high sediment supply can produce thick sequences that contain detailed information on the controlling sedimentary processes. However, the stratigraphic record must be unraveled to understand the terrestrial and marine processes influencing sedimentation. As part of the multi-institutional MARGINS “Waipaoa Investigation of Seabed Energetics” project, time-series analysis of surficial seabed properties (e.g., erodibility measurements, x-ray radiography, and sedimentological and radiochemical data) are being used to evaluate temporal and spatial changes in strata formation and sediment dynamics on the Waipaoa River margin. Data indicate significant temporal-spatial variability in seabed properties reflecting a dynamic sedimentary environment, especially proximal to Poverty Bay. Stations located near the mouth of Poverty Bay are characterized by heterolithic deposits and often show greater erodibility in comparison to other sites (e.g. those in the mid-shelf depocenters) that have higher clay percentages. Temporal changes in physical sediment properties appear to be caused by short-term deposition and erosion of sediment which is controlled by fluvial supply and oceanographic conditions. Measurements of seabed properties (e.g., erodibility) will be incorporated into modeling efforts to predict sedimentation in this morphologically complex system. (Abstract ID 11727)

IMPACT OF WINTER SST ANOMALIES ON EASTERN SEABOARD SUMMER SURFACE WIND VARIATIONS
The direction of summer winds plays a key role in a wide array of physical and biological processes. Using a 60-year time series of winds observed at nine stations along the US East Coast, we demonstrate how the large-scale variability in inter-annual summer wind direction is linked to climatological forcing. Using NCA/NCEP reanalysis data, we have documented that the prevalence of winds from the south along the majority of the Eastern Seaboard is related to sub-heating in the location and intensity of the Bermuda High. South winds are favored when the Bermuda High intensifies and builds northwest over New England. In contrast, during summers when the Bermuda High is weaker over New England, north winds become more common. The large-scale variability of the Bermuda High is linked to SST anomalies from the previous winter. We propose a mechanism by which cold winter SST anomalies intensify the Bermuda High during the following summer favoring winds from the south, while warm winter SST anomalies limit the northwest expansion of the summer Bermuda High reducing the occurrence of winds from the south. AN AIR-SEA FLUX EXPERIMENT FOR 2030
In January 2011 the University of Rhode Island held a two day retreat for faculty and research scientists interested in where the field is going over the next 20 years. The retreat began with presentations detailing the current status and anticipated advances in genetics, nanotechnology, numerical modeling and robotics. Participants then outlined scientific problems that they expect will exist in 2030. This was followed by breakout sessions in which participants discussed experiments, based on anticipated technological advances, that might be undertaken in the 2030 time frame to address some of the identified problems. In this presentation we outline one of these experiments. The experiment was designed to quantify air-sea fluxes under high wind conditions following a wave train. We believe that not only will the processes involved remain poorly resolved in 2030 but also that they will become of increasing importance as the coupling and the spatial and temporal resolution of ocean and atmospheric models improves. The experiment outline is based on a suite of unmanned submersible and air assets designed to sample the ocean, the atmosphere and the interface between the two. (Abstract ID 12464)

HALOBATES IN THE EASTERN TROPICAL PACIFIC 1967-2010: AN UPDATE ON DENSITY AND EVIDENCE FOR SEASONAL RANGE SHIFT
Five species of the marine insect Halobates are adapted to life on the open ocean. Four of these species live in the Eastern Tropical Pacific Ocean. The distribution and density of Halobates in the Eastern Tropical Pacific was investigated using a 10 year data set collected from the Sea Education Association’s sailing research vessel SV Robert C. Seamans. These data, now compared to the EASTROPAC Halobates dataset from 1967-68. Data for two species, Halobates sobrinus and Halobates micans, suggest rather than a change in distribution in the last 45 years, Halobates in the region shift their range seasonally. As many have suggested previously, sea surface temperatures appear to affect the range of Halobates. The surface current structure in the region also may help control distribution. The low co-occurrence in net tows suggests monospecific aggregations even when the ranges of two species overlap. Halobates density shows significant inter-annual variation though the causes remain unclear. (Abstract ID 11174)
FORAGING BEHAVIOR OF A WIDELY RANGING MESO-PELAGIC TOP PREDATOR, THE NORTHERN ELEPHANT SEAL.

The mesopelagic zone of the northeast Pacific Ocean is an important foraging habitat for many predators, yet few studies have addressed the factors driving basin-scale predator distributions or inter-annual variability in foraging and breeding success. We collected diving, tracking, foraging success, and natality data for a large number of adult female northern elephant seals over seven years. Mean foraging success varied by factor of two across years and was a significant predictor of natality. At sea, behavioral foraging metrics based on diving and tracking data suggest the boundary between the sub-arctic gyre and subtropical gyre contains a rich and persistent prey resource at mesopelagic depths, but a small proportion of seals were also successful north of the boundary in the sub-antarctic gyre and neighboring continental shelf breaks. Seal density distributions and temperature profiles show a strong association with the gyre-gyre boundary during both annual migrations, consistent with previous reports that the latitude of the gyre-gyre boundary is stable relative to dynamic surface features, such as the transition zone chlorophyll front. MODIFICATIONS OF A SOUTH ATLANTIC OCEAN WARM-RING BY AIR-SEA INTERACTION

Two different models were used to investigate the modifications in the thermostat of a warm Agulhas ring by air-sea interaction in the South Atlantic Ocean: a one-dimensional mixed layer model (PFWP) and a realistic OGCM (ROMS), with surface forcing from NCEP climatological and synthetic data. The ring was sampled three time by the High Density XBT Transects (AX18), which shows that the 16°C thermostat reaches 220 meter depth in July 2000, and extends down to 310 meter depth in January 2010. The impact of the surface flux induced secondary circulation within the ring is investigated in the deepening of the thermostat and the formation of a subsurface velocity maximum. This effect is supported by geostrophic velocities calculated with temperature and salinity XBT section and absolute AVISO SSH. The synoptic-scale surface forcing is necessary for a good simulation of the ring thermal balance, since large heat fluxes out of warm-core rings can be expected during atmospheric fronts or storms. (Abstract ID 12295)

FUTURE OCEAN USES IMPORTANT FOR COASTAL AND MARINE SPATIAL PLANNING

There is a need to conserve ocean ecosystems and use ocean space, requiring planning for multiple uses of compatible activities and development of strategies to promote, enhance, and optimize these uses. The Rhode Island Ocean Special Area Management Planning (OSAMP) process is an ecosystem-based planning framework with unique policy drivers. The OSAMP also informs implementation actions for future multiple uses of ocean space. The OSAMP reviewed possible future uses and conservation issues for Block Island and Rhode Island Sounds: mining, offshore LNG, short sea shipping, marine conservation, artificial reefs, aquaculture development, expansion of ecotourism and underwater cemeteries, and use as a research/education area. Principles and practices of ecological engineering, industrial ecology, life cycle assessments and material flow accounting, as well as social ecology and ecological economics will be important to the design, implementation, and evaluation of compatible, multiple uses of ocean space. There will also be a rapid turnover of ideas on the future uses of ocean space; thus, a participatory framework for the engagement of stakeholders must continue as new uses are explored so that all information can be shared systematically. PHYSICAL PROCESSES DRIVING FINESCALE BIOLOGICAL PATCHINESS IN AN INNER SHELF, HIGH PRODUCTIVITY ENVIRONMENT: ACOUSTIC AND OPTICAL MEASUREMENTS

As part of an interdisciplinary effort to define lateral mixing in an inner shelf area previously studied for its development of plankton thin layers, we conducted finescale sampling using acoustics (Simrad 200 kHz and 710 kHz) and an undulating optical imaging system (ISIS) in...
the northeast Monterey Bay over a 12-d period. Acoustic observations revealed considerable spatio-temporal variability in the vertical extent of fine layering of the water column; some days were characterized by well-defined thin layers (ca. 1 m thick), while other days the water column was acoustically homogeneous (ranging from dense returns to very light returns). Optical observations of the water column revealed extremely dense phytoplankton aggregations (dominated by *Pseudo-nitzschia spp*), with extensive flocculation (ca. 1-2 cm diameter) concentrated at thin layers. Flocs were also abundant where strong acoustical returns occurred throughout the water column. Zooplankters (e.g. copepods, shrimp, etc.) were distinctly absent from most of these thin, subsurface layers, though concentrations of copepods were occasionally evident near the surface. Alteration of the water column was driven by lateral intrusion of offshore water and stirring of a non-bloom water mass. (Abstract ID 11092)

OCEAN OBSERVATORIES INITIATIVE: CONSTRUCTION PROGRESS UPDATE
The National Science Foundation’s (NSF) Ocean Observatories Initiative (OOI) is implementing the construction and operation of an interactive, integrated ocean observing network. Construction funding for this research-driven, multi-scale network began in September, 2009. The OOI is constructing instrumented networks of multidisciplinary sensors on moorings, autonomous underwater vehicles, gliders, and seafloor platforms. During the past year, major advances occurred across the project. The OOI now has an implementing organization to develop education infrastructure. $880$ km of underwater cable was installed across the Juan de Fuca plate off the Oregon coast and a cable station at Pacific City, OR was established. Several at-sea tests of essential design elements for coastal and global moorings were conducted off the Oregon coast and south of New England. Considerable test data will be available in late 2011 and into 2012. Gliders are being purchased and tested for deployment in 2012, with data flowing by fall 2012. Over half the instrument types to be installed during construction have been identified. Workshops and webinars will occur on a regular basis. More information at http://www.oceanobservatories.org (Abstract ID 12086)

INTERRUPTED TURBULENCE AND SEDIMENT SUSPENSION IN THE SURF ZONE AND IMPLICATIONS FOR ONSHORE SEDIMENT TRANSPORT
Wave breaking turbulence and sediment suspension in the surf zone are characterized by large intermittent events. We analyzed cross-shore observations of velocity and sediment concentration from a large-scale laboratory experiment (CROSSTEX) under erosive and accretive wave forcing to investigate the conditional probabilities between wave breaking turbulence and sediment suspension. Approximately 30–65% of the sediment suspension events were associated with turbulent events, implying that intermittent turbulent motion is one of the fundamental mechanisms for the initiation of sediment suspension in the surf zone. The uncorrelated sediment suspension events were associated with strong offshore currents, consistent with advection. One notable exception was at the bar trough in the accretive case, implying that additional mechanisms for the initiation of sediment suspension are important. For the accretive case, the large intermittent sediment suspension events contributed to a net onshore transport near the bar. We developed a time-dependent model of intermittent sediment suspension for both cases using an artificial neural network to explore the contribution of the slowly varying undertow, wave induced velocity, and turbulent kinetic energy on sediment suspension across the surf zone. THE INFLUENCE OF NEARSHORE BARS ON INFRAGRAVITY ENERGY AT THE SHORELINE
Bathymetric features such as nearshore sandbars can alter local nearshore hydrodynamic processes such as the production of infragravity energy. These bathymetric features may act to reduce or increase the amount of infragravity energy that reaches the shoreline. To determine the influence of the bathymetric features on infragravity energy, the numerical nearshore processes model XBeach was used to simulate infragravity energy at the shoreline. Numerical simulations were completed for three types of bathymetric scenarios: continuous alongshore bar, 1-2 rip, and no-bar. An empirical parameterization for significant infragravity swash developed by Stockdon et al. (2006) was modified for barred beaches. Results show that the amount of infragravity energy in the form of swash is dependent on the bar height and depth, in addition to the offshore wave height and wavelength. Since infragravity swash influences beach erosion (Rovinskii et al. 2009, Ruggiero et al. 2006), results of this research may be used as part of an erosion vulnerability scale. Such information on erosion vulnerability is important for the design of coastal protection systems and the protection of coastal communities. (Abstract ID 9349)

BIOLUMINESCENCE IN THE NEAR SEAFLOOR REGION OF THE DEEP SEA.
Bioluminescent activity has been reported to be very low in the absence of artificial stimulation. However, bioluminescent zooplankton, advected by currents, are stimulated to produce light as they impinge on overtopping features on the seafloor. The rate of bioluminescent flashes is dependent on the size of the overtopping feature, the current speed and the BL density. Low-light video imaging systems were used to quantify the density of bioluminescent zooplankton (BL) in the near seafloor region (0-400 m above bed). BL density was found to decrease exponentially with seafloor depth, by a factor of 4.2 per 1000 m in the Mediterranean Sea ($R^2=0.92, P<0.0001$) and by a factor of 3.5 in the Atlantic Ocean ($R^2=0.89, P<0.0001$). At equivalent depths, BL densities in the N Atlantic Ocean were consistently higher than those in the Mediterranean Sea, reflecting the lower productivity of the latter region. Novel predictions can be made of the visual environment of the deep-sea floor using high resolution bathymetric maps, current data and BL density depth trends. (Abstract ID 12580)

THE 3-MINUTE SOLUTION: COMMUNICATING YOUR RESEARCH IN SHORT, EFFECTIVE VIDEOS
The fact that changes are occurring in the ocean provides both a unique opportunity and urgent need for ocean and coastal scientists to communicate their research to a broad audience. Some of these changes affect us in our daily lives - more intense hurricanes, drought, dead zones, depleted fisheries – making the connection to research more obvious. Connections to daily life mean more people are more concerned, yet that places additional pressure on ocean scientists to be able to communicate effectively. With the rise of YouTube and other online outlets, short videos have become a part of the daily information stream for students, educators, and citizens. Video has been used effectively in a variety of settings, and we will offer examples: online teaching, aquarium kiosks, live broadcasts from research cruises, educational websites, audio slideshows. But making an effective video is not as simple as turning on the camera. We will present the COSEE OCEAN template: how to produce an engaging video, featuring a scientist communicating their research clearly, that will capture the attention of a broad audience in under three minutes. SOME LIKE IT HOT, SOME LIKE IT COLD: THERMAL FLEXIBILITY IN CORAL SYMBIOTS
The symbiosis between coral hosts and zooxanthellae forms the foundation of coral reef ecosystems. Translocation of photosynthates, including sugars, amino acids, and lipids, from symbiont to host signals coral health and may be responsible for light enhanced calcification. In shallow waters, photosynthetic symbiont production can exceed the requirements for symbiont to host signals coral health and may be responsible for light enhanced calcification. In deeper, lower light waters, algal symbiont photosynthesis slows and may provide lower levels of essential nutrients and energy to the host. Extreme temperatures can have devastating impacts on coral symbiosis by causing bleaching. We used high-resolution GC-MS metabolomics to compare metabolite signals in four clades of symbionts (A, B194, B224, and D). Symbiont production of metabolites varies with light and temperature. Thermally tolerant Clade D differentiates itself from other clades. Clade D produces high energy fatty acids, even in high light stress when Clade A and B184 greatly reduce fatty acid production. Clade B224 shows promise as a thermally and light tolerant symbiont. (Abstract ID 10826)

NEXT-GEN PHYLOGEOGRAPHY
Phylogeography has emerged over the last two decades as an exciting and informative field that spans the chasm between population genetics and systematics. Population genetics has traditionally been interested in the processes of evolution, including estimated associated parameter values such as migration rates, genetic diversity, and measures of selection; systematics has focused on historical patterns of divergence and associated morphological,
temporal, and ecological changes correlated with such patterns. Phylogeography attempts to merge these perspectives and capitalizes on gene divergence patterns and their fit to predictions derived from different models in population genetics. The seminal work of Avise and colleagues ushered in this approach to merging concepts from these two fields to study speciation and population divergence. Over the past two decades, an impressive set of analytical tools have been developed with advances in both population genetics and phylogenetics that have had a significant impact in phylogeography. Recently, significant advances in DNA sequencing technologies have revolutionized the scale and scope of genetic data that can be used to study phylogeography and population genetics. Here I overview the methodologies, both molecular and analytical, for phylogeographic inferences and provide examples of applications of such methodologies to natural history studies. RECONSTRUCTION OF MARINE FISHERIES CATCHES FOR TUVALU (1950-2009)
Tuvalu’s total marine fisheries catches within its EEZ were reconstructed for the years 1950 to 2009. This reconstruction accounts for officially un- and underreported catches of artisanal and subsistence fishery sectors as well as the baitfish used in the pole-and-line tuna fishery. FAO data were used in combination with data from fish markets, regional reports and consumption data. Total reconstructed catches were estimated to be 66,631 over the six decades, which is approximately 5 times larger than the amount reported by the FAO to Tuvalu’s behalf (12,241 t). Total catches increased from 83 t/year-1 in 1950 to 1,607 t/year-1 by 2009. The majority of total catches were from the subsistence sector (87%). Although the subsistence sector was the principal portion of the reconstructed catch, it was largely excluded from the reported data. This investigation reveals the need for an improvement in the accounting of marine fishes total catches were from the subsistence sector (87%). Although the subsistence sector was the principal portion of the reconstructed catch, it was largely excluded from the reported data. This investigation reveals the need for an improvement in the accounting of marine fishes.ubc.ca

WATER COLUMN METHANE DYNAMICS IN RESPONSE TO THE DEEPWATER HORIZON HYDROCARBON SPILL
The Macondo Blowout injected as much as 500,000 tonnes of natural gas into the Gulf of Mexico water column. To determine the impacts and the fate of this massive injection of gas, we measured the methane concentration and the rates of aerobic methane oxidation during several expeditions following the BP oil spill from early May until December 2010. In situ dissolved methane concentrations were determined using headspace extraction and gas chromatography, and methane oxidation rates were determined using the tritiated methane radiotracer technique. Aerobic methane oxidation rates peaked within methane rich subsurface plumes in late May (58 nmol/L) but decreasing significantly by late June (less than 50 nmol/L) throughout the water column. The quantification of methanotrophic populations by quantitative PCR revealed an increase in the methanotrophs 16S rRNA gene copy number that corresponded to the observed patterns in increase of the methane oxidation rates. Quantification of the pmoA gene (encoding particular methane monooxygenase subunit A) over time, as well as laboratory experiments identifying environmental factors regulating the methanotrophic community, provided insight to the factors regulating methane cycling in Gulf of Mexico waters. HOOKING UP: THE ROLE OF FLUID STIRRING AND CHEMOTAXIS IN EXTERNAL FERTILIZATION STRATEGIES
Many benthic invertebrates reproduce via an external fertilization strategy called broadcast spawning. Males and females release sperm and egg at separate locations, and subsequent fertilization relies on structured fluid stirring (at large scales) and chemically mediated sperm taxis (at small scales) to bring gametes into contact. Past studies by our group show the role of fluid stirring on bringing initially distant gametes into close proximity. However, these same studies show that, due to the weakly diffusive nature of egg and sperm, actual coalescence of gametes by stirring and mixing alone is limited. This suggests that sperm chemotaxis is critical for efficient fertilization. We present a set of analytical, numerical, and laboratory experiments that demonstrate how physical processes cause gametes to aggregate. We then demonstrate how sperm taxis acts as a "directed diffusion" at small scales that greatly enhances the resulting fertilization rate. The goal is to show the effect of complex flows on the resulting distribution of attractant plume exuded by eggs, and how sperm taxis parameters like swimming speed and attractant sensitivity impact the resulting fertilization success rate. FORMATION AND EROSION OF THE SEASONAL THERMOCLINE IN THE KUROSHIO EXTENSION RECIRCULATION GYRE
Data from the Kuroshio Extension Observatory (KEO) surface mooring are used to analyze the balance of processes affecting the upper ocean heat content and surface mixed layer temperature variations in the recirculation gyre (RG) south of the Kuroshio Extension (KE). Cold and dry air blowing across the KE and its warm RG during winter cause very large heat fluxes out of the ocean that erode the seasonal thermocline in the RG. Some of this heat loss is replenished through horizontal heat advection. Enhanced diffusive mixing at the base of the mixed layer tends to transfer heat downward, potentially eroding and even modifying subtropical mode water. Diffusivity at the base of the mixed layer, estimated from the residual of the mixed layer temperature balance, has values of $3-5\times10^{-4} m^2/ s$ during the summer and values a couple of orders of magnitude larger during winter. The enhanced diffusivities appear to be due to large inertial shear generated by wind events associated with winter storms and summer tropical cyclones. (Abstract ID 10084)

CARBONATE MINERAL SUPPRESSION AND OCEAN ACIDIFICATION IN THE EASTERN BERING SEA
Increasing CO$_2$ concentrations in the atmosphere and ocean have induced an anthropogenic acidification phenomenon, particularly in high latitude seas, commonly resulting in suppression of carbonate mineral saturation states. On the Eastern Bering Sea shelf, several natural mechanisms of carbonate mineral saturation state suppression have been observed, including the upwelling of low pH deep water onto the shelf; the influx of low pH river water to the coastal margin; and a highly productive biological pump, which seasonally lowers pH in bottom waters and increases atmospheric CO$_2$ absorption in surface waters particularly over the middle shelf. The anomalous occurrence of coccolithophore blooms in recent years may also contribute to carbonate mineral suppression in the region by lowering surface ocean alkalinity and reducing buffering capacity. Here we use $^{818}O$ tracer data to distinguish the impact of these blooms on carbonate mineral saturation states in the Eastern Bering Sea. Despite the presence of these various naturally occurring mechanisms of carbonate mineral suppression, we show
that it is ultimately the addition of anthropogenic CO₂ that results in seasonal undersaturations of carbonate minerals to this system. (Abstract ID 9529)

INVESTIGATING THE TEMPORAL VARIABILITY OF SUSPENDED PARTICLE POPULATIONS IN A SHALLOW SHELF SEA

The majority of the energy associated with tidal activity is dissipated within shelf seas, though they occupy a relatively small area when compared to the expanse of the open ocean. The dynamics of suspended particulate matter (SPM) in a shallow shelf sea environment are explored across a spring-neap-spring cycle during the onset of seasonal stratification. A vertical microstructure profiler was used to measure several turbulence parameters, whilst near-simultaneously a subsurface holographic imaging system recorded the number and type of SPM (inorganic flocs, phyto and zooplankton). The response of SPM to the changeable physical domain has been observed, highlighting the degree to which temporal variability in SPM populations exist through resuspension events and interaction with the complex, vertically sheared flow regime. Analysis of the size and distribution of specific groups of SPM across the tidal cycle is made possible with the application of bespoke particle identification and enumeration software. Advection of small-scale lateral gradients in SPM populations is assessed through use of the biogeochemical models of the General Ocean Turbulence Model (GOTM). (Abstract ID 9717)

RETROSPECTIVE ACCESS TO OPERATIONAL US. OCEAN MODEL PRODUCTS THROUGH THE OCEANOMADS SYSTEM

OceanOMADS is an archive and access system for operational ocean model output, associated with the National Oceanic and Atmospheric Administration (NOAA) National Operational Model Archive and Distribution System (NOMADS). The project is collaborative and distributive: three principal partners each contribute in ways that reflect their individual strengths and missions. The NOAA National Weather Service provides real-time access to NOAA and Navy operational model products via the National Centers for Environmental Prediction. A research and development component is provided through the Ecosystem Data Assembly Center at the Northern Gulf Institute, a NOAA Cooperative Institute. Finally, long-term preservation and retrospective access are provided by NOAA’s National Coastal Data Development Center (NCCDC), a division of the National Oceanographic Data Center. This presentation focuses on the data catalog and services that comprise NCCDC’s OceanOMADS (http://www.nodc.noaa.gov/ocean-nomads/), as well as plans for its future development. The current data collection includes several years’ worth of daily operational model runs from NOAA and Navy, as well as NOAA’s recent 30-yr reanalysis. We give examples of data services provided, including basic visualization, spatial and temporal subsetting, and timeseries aggregation. (Abstract ID 11986)

NEAR-BOTTOM OCEAN CURRENT PROFILES IN THE NORTHERN GULF OF MEXICO

Federally-mandated ocean current profiles from oil and gas platforms in the northern Gulf of Mexico provided important information for the tracking of surface and deep oil from the Deepwater Horizon incident. These current profiles, which extend from the surface to approximately 1000 meters depth and from the bottom upward in deeper locations, are available from NOAA’s National Data Buoy Center. Although the data were collected in order to enhance safety and redesign of the offshore platforms, the data, collected at sub-hour intervals, provided a unique data set for supporting the Deepwater Horizon response. The data set is also appropriate for investigating the oceanography of the northern Gulf of Mexico. Analyses of the deepwater data show wind-generated inertial currents traveling throughout the water column and impacted by bottom friction. Weak tropical storms and major hurricanes (Katrina, Rita, and Wilma) generate above-background currents at three locations with depths ranging from 1100 to 1300 to 1950 meters. Time series analyses of a near 5-year record of near-bottom currents indicate the presence of topographic Rossby waves near 27.3N. (Abstract ID 11919)

THE OCEAN OBSERVATORIES INITIATIVE EDUCATION AND PUBLIC ENGAGEMENT: DELIVERING REAL TIME DATA FOR TRANSFORMATIVE LEARNING IN THE UNDERGRADUATE CLASSROOM

The Ocean Observatories Initiative (OOI) will reshape the way ocean science is conducted. Recent advances in the delivery of web-based education, and use of visualization technology and data visualization tools in educational contexts, have led to the development of on-line platforms for instruction that engages students in active scientific inquiry by collecting and analyzing data of real world phenomena. The OOI Education and Public Engagement (EPE) Implementing Organization will leverage these technologies for ocean education. As the OOI develops and deploys transformative tools necessary to understand the changing oceans, it will also enable the effective translation of results into understandable information usable by educators and potential workforce participants. To this end EPE will construct a series of software tools and a web-based social network to support engagement of a wide range of education users and free choice learners. These tools will enable them to enhance their undergraduate education and engage the free choice learners using real-time and streaming data provided by the OOI. (Abstract ID 10528)

POSSIBLE CLIMATE CHANGE IMPACTS ON SUPPLY OF MICRONUTRIENT IRON TO THE GULF OF ALASKA

It is well documented that glaciers near the Gulf of Alaska (GoA) have been rapidly losing mass, yet the impacts on the ocean are not well understood. One possible impact is altered transport of iron, an essential micronutrient that limits productivity in much of the GoA, since glacial flour is a source of iron to the ocean in rivers as well as dust. Yet there are very few iron data from this part of the ocean, hence iron sources are poorly quantified. Here we will present recent work from the coastal GoA, including iron and nitrate profiles, as well as surface-water concentrations, from cruises spanning a transect from the mouth of the Copper River to beyond the continental shelf. We will discuss sources of iron from the coastal ocean (rivers, sediment resuspension) as well as various mechanisms by which this iron can be transported beyond the continental shelf, to deeper, iron-limited waters (currents, eddies, dust). We will share thoughts on how some of these processes might change in response to melting glaciers and climate change, and possible impacts on productivity. (Abstract ID 11798)

The sea-water from Gulf of Trieste has a low pCO2 due to a high pCO2 consuming activity, which is
related to high salinity. By reducing the pCO2 level in the Basin, the pCO2 consuming activity
increases and the higher pCO2 level is reached. The decreases in pCO2 levels are due to the
increase of primary production and heterotrophy. This increase is related to the decrease of
suspended particulate matter (SPM) and algae. This decrease is due to the increase of salinity
and temperature. The decrease in pCO2 levels is not related to the increase of pCO2 consumption
by carbonate compensation or the increase of pCO2 exchange. The decrease in pCO2 levels
is related to the increase of primary production and heterotrophy. This increase is related
to the decrease of SPM and algae. This decrease is due to the increase of salinity
and temperature. The decrease in pCO2 levels is not related to the increase of pCO2 consumption
by carbonate compensation or the increase of pCO2 exchange. The decrease in pCO2 levels

N-LOADING, CHLOROPHYLL AND PERSISTENT HYPOXIA IN THE CHESAPEAKE BAY
We studied early summer chlorophyll and oxygen concentrations in the main stem of the
Chesapeake Bay from 2001 to 2011. Mean chlorophyll values ranged from 8.6 μg/l in 2002, to
40.1 μg/l in 2003 and averaged 19.5 μg/l (SD = 10.3). Stepwise regression revealed chlorophyll in the upper 8 m was best explained by N loading (P = 0.047), somewhat influenced by salinity
(P = 0.084), and unaffected by either temperature (P = 0.436) or year (P = 0.746). Oxygen levels below 5 m declined nearly 50% between 2001 and 2004, remaining low through 2011. The
decline fit a model of hyperbolic decay (F=(a)(b)/(x+b)), R2 = 0.90, P < 0.0001. N loading did not
explain oxygen depletion below 5 m (P=0.98). Oxygen demand from sediments enriched by
benthic respiration may explain the trends of contemporary N loading. Overall, the last decade,
surface oxygen levels (above 8 m) correlated positively with chlorophyll concentrations (R2 =
0.78, P = 0.0007), reflecting the importance of photosynthetic contributions to the oxygen budget in the photic zone. (Abstract ID 9424)

A 15-year time series of microbiogeochemical ecophysiological measurements involving
sediment, nutrients, plankton, productivity, and benthic community components straddles
several major ecosystem perturbations. One of these, in a benthic kensia bivalve muscle, led to rapid oligotrophication of a 58,000 km2 basin and collapse of its commercial and now even sport fisheries. Biomass diversion from plankton to benthos was also evident in lower total and particulate (biomass) phosphorus offshore. Research education and citizen science activities have provided many measurements of community structure as length-frequency relations that are easy to measure accurately by novices. Since the beginning of the invasion, less prolific datasets for morphometry-composition relations (morphometry: wet weight, dry weight, elemental composition as a function of length) have been developed. Consistent biogeochemical composition was found among inhabitants of disparate benthic character (rocky, sandy, silty, clay) and over the full range of ecological competition (from pioneers to
total dominance) during the first 10 years of establishment. This expands the value of a million length measurements to estimation of basin-scale food web alteration. How many quaggas does it take to make a walleye? (Abstract ID 10893)
before being passed to the CESM coupler. Results will be presented from a 100 year simulation of the nRCM, with the ROMS domain covering the north-east Pacific. Comparisons with a standard CESM run reveal significance of maintaining two-way coupling for regional downscaling in that the nRCM provides statistically significant reductions of the warm SST bias offshore of the California/Oregon coast which induces changes in the atmospheric boundary layer and far field (up-scaling) effects in the tropical Pacific and north Atlantic oceans. (Abstract ID 11931)

TOWARD A UNIFIED AIR-SEA INTERFACE FOR FULLY COUPLED ATMOSPHERE-WAVE-OCEAN MODELS AND TROPICAL CYCLONES PREDICTION
One of the most challenging issues in understanding and modeling of tropical cyclones is the representation of fully coupled air-sea interactive processes in numerical models. The study aims to develop a unified air-sea interface for fully coupled atmosphere-wave-ocean models, which is physically based and flexible to use for development of new physical parameterizations of wind-wave and wave-current coupling in high-wind conditions. It takes advantage of the recent advancement in the applications of the Earth System Modeling Framework (ESMF) in a multi-model system that includes the Weather Research and Forecasting (WRF) model, the Hybrid Coordinate Ocean Model (HYCOM), and the University of Miami Wave Model (UMWW). The main objective of this study is to better understand the momentum transfer across the air-sea interface in tropical cyclones. Coupled atmosphere-wave-ocean model experiments of Hurricane Ike (2008) are used to examine the effects of air-sea coupling on hurricane structure and intensity change. (Abstract ID 12883)

OBSERVATIONAL STUDY OF THE FLUX AND WATER MASS VARIABILITY THROUGH DAVIS STRAIT
An ongoing observational program to quantify volume, freshwater and heat exchange between the Arctic and North Atlantic Oceans through Davis Strait has been operational since September 2006. The year-round program consists of velocity, temperature and salinity measurements from 15 moorings spanning the full width of the Strait. Over the shallow Baffin Island and West Greenland shelves, novel moored instrumentation provides temperature and salinity near the ice-ocean interface. Autonomous gliders improve the spatial resolution (average profile separation = 4 km) of the array and have captured the first high-resolution wintertime sections across the Strait. No clear trends are observed in the 2006-2010 net fluxes. However, more recent data (2008-2010) suggest an increase in Arctic freshwater discharge through Davis Strait, consistent with decreasing freshwater inventory within the Beaufort gyre. Interannual flux variability is large and mean (+ standard deviation) volume, freshwater and heat fluxes are -1.4 ± 0.2 Sv, -89 ± 16 mSv and 23 ± 4 TW, respectively. Net volume and freshwater transports through Davis Strait are similar in magnitude to those estimated for Fram Strait, the other major Arctic gateway. (Abstract ID 11794)

BRACHIOPODS RECORDING SEAWATER TEMPERATURE – A MATTER OF MATURATION?
The stable, low-magnesium shells of brachiopods and their long geological record means that they are an attractive source of past seawater temperature data. Indeed, these attractive features have been exploited by employing brachiopods in a wide range of palaeo-environmental studies. With brachiopods, as with all biological proxy systems, caution is required in order to separate out biological and kinetic influence from environmental data. This paper considers the recording of seawater temperature in modern brachiopods in known water conditions in the context of biomineralisation. Consideration is given to the kinetics of shell formation, biological control on crystallography as well as shell structure, perforations and maturation of brachiopods in order to tease these factors apart and identify a robust strategy for extracting seawater temperature data. NON LINEAR INTERNAL TIDES, SOLITARY WAVES AND TURBULENT MIXING IN THE CONTINENTAL SHELF OF SOUTH BRITTANY
In July 2010 the PerZong campaign was set up in South Brittany (Bay of Biscay) in order to assess the impact of strong internal tides, solitary waves and associated turbulent mixing on the phytoplankton distribution on the continental shelf. High frequency measurements of CTD and currents were performed at two locations (65 m depth and 25 m depth), in addition turbulent dissipation and vertical eddy diffusivity were estimated using microstructure measurements. During spring tide semi diurnal internal tides evolved into nonlinear fronts and solitary waves at both locations. At the deepest location a large vertical mode 2 response was associated with nonlinear fronts resulting in a splitting of the pycnocline and large overturns. These frontal structure were followed by train of high frequency waves with a few minutes period. At the shallowest mooring vertical mode 1 was dominant and frontal structure and solitary waves seem to result from a more classical steepening process as described in the KDV framework. At both location nonlinear waves were associated with large values of dissipation ($epsilon=10^{-6} W/kg$) within the pycnocline suggesting a strong impact on mixing. (Abstract ID 11476)

HYDRODYNAMIC ROUGHNESS AND BED STRESS OVER CORAL REEFS
The highly irregular and spatially variable roughness characteristic of coral reefs results in high dissipation rates and associated high drag for waves and currents. Several field studies have been carried out over coral reefs in a variety of locations around the tropical Pacific with the objective of examining the relationship between physical bed roughness and the hydrodynamic response for reef environments. The beds at each site are characterized by highly inhomoogeneous roughness. Physical roughness is surveyed over large areas using AUV based altimeter observations. Boundary layer turbulence is measured at each study site using a bottom mounted vertical spar with three ADVs while velocity profiles are measured using a nearby ADCP. Bed stress associated with the steady flow is estimated from the ADV data using the inertial dissipation method and from the ADCP data using logarithmic fits to the mean profiles. Here we summarize the results of the data analysis and present estimates of bed stress and hydrodynamic roughness scale from the multiple study sites. These results are then related to AUV-based measurements of physical roughness. (Abstract ID 12263)

INTERIOR VERSUS BOUNDARY MIXING FOR THE EROSION OF A COLD INTERMEDIATE LAYER IN A SUBARCTIC ESTUARY
The relative importance of interior versus boundary mixing is examined for the cold intermediate layer (CIL) in the St. Lawrence Estuary. CIL erosion rates were calculated using 18 years of historical weekly temperature profiles. Per month, the CIL thickness decreases by 11 m, its core temperature warms by 0.2 degrees and its heat content increases by 0.6 MJ/ m$^3$. These erosion rates are remarkably well reproduced with a 1D vertical diffusivity model with a mean turbulent diffusivity inferred from around 1000 turbulence profiles collected during summer 2009 and 2010. These measurements were collected within the interior and
near lateral boundaries, where the CIL intersects the sloping bottom. The analysis suggests that interior mixing alone accounts for about 70% of the diffusivity required to reproduce the erosion rates with the 1D diffusion model, with the remainder being attributed to boundary mixing. We conclude that while boundary mixing may be significant it does not seem to dominate CIL erosion. (Abstract ID 11240)

A NEW MECHANISM FOR OCEAN ATMOSPHERE COUPLING IN MIDLATITUDES

The role of moist convection in "transferring" upward surface ocean conditions throughout the troposphere is studied using reanalysis data for the extratropical Northern and Southern Hemispheres in winter. It is found that conditions for the development of a convective air column from the sea surface to the tropopause are met frequently over all major western boundary currents and their extension in the ocean interior (sometimes for as much as 50% of the time). These frequent occurrences are shown to be jointly controlled by oceanic advection of warm waters and, on the atmospheric side, the downward displacement of the tropopause associated with synoptic weather systems. Based on these results, it is proposed that the oceans can influence the atmosphere directly through convection in midlatitudes, as is commonly thought to occur in the Tropics. Analysis of the Richardson number Ri found at low levels suggests that moist symmetric instability (0 < Ri ≤ 1) is a key process involved in linking surface ocean temperatures to atmospheric lapse rates, in addition to standard upright convection. These low Ri processes are not currently parameterized in climate models, which raises the possibility that the extratropical oceanic influence on climate might be underestimated in the current generation of models. (Abstract ID 11428)

The effect of natural ocean surfactants on bubble fragmentation and coalescence

The plumes of bubbles generated by breaking waves in the ocean are thought to influence marine aerosol production, air-sea gas transfer, and both the optical and acoustical properties of the upper ocean. One of the major uncertainties in the current understanding of these bubbles plumes is the effect of natural surfactants. These chemicals are produced by marine life and will accumulate on surfaces, including the surfaces of bubbles, changing the surface physical properties. It is thought that the presence of surfactants may change bubble plumes significantly, by altering bubble formation processes and by slowing bubble dissolution. However, there is not currently enough information to predict these changes or their importance. This study is a step towards understanding the effects of natural surfactants on ocean bubble plumes, and the consequences for gas exchange and aerosol production. In the future, it may be possible to use observations of ocean bubbles to measure some of the properties of the natural surfactants present. Using very clean apparatus, individual bubbles of different sizes were either fragmented or smashed together by turbulence in the presence of different surfactants. Fragmentation is known to be the main mechanism generating new large bubbles underneath breaking waves, so studying the effects of surfactant on this process should provide insight into the generation of natural bubble plumes. Using the results of these experiments, the effects of those surfactants on an entire bubble plume are predicted. The next stage of this study, not presented here, will be to test those predictions in wave tanks and the open ocean. (Abstract ID 9942)

LONG-TERM OXYGEN CHANGES IN THE EQUATORIAL EASTERN PACIFIC

Observations indicate increasing oxygen minimum zones (OMZs) in the tropical Pacific over recent decades. A comparison of repeated hydrographic sections in the eastern tropical Pacific at 110°W and 86°W demonstrates that enhanced oxygen is related to stronger eastward flow at some locations, but not at others. Oxygen generally decreases below the surface layer in the tropics at the 110°W and 86°W sections. Historical data are quite sparse for constructing oxygen time series, but floats with oxygen sensors prove to be good tools to fill measurement gaps in later portions of these time series. In the future, floats with oxygen sensors might play an important role in allowing construction of nearly continuous time series in regions with sparse or infrequent ship-based hydrographic surveys. In the eastward flow region just south of the equator, a time-series constructed from historical and float data reveals oxygen decreasing from 200–700 m depth at up to 1.9 µmol kg−1 over the last 34 years. Oscillations on shorter time scales, e.g. an El Nino signal in the upper 350 m, are superimposed upon this trend. (Abstract ID 9680)

STORM SURGE MODELING IN THE CHESAPEAKE BAY DUE TO THE PROBABLE MAXIMUM HURRICANE

The characteristics of the Probable Maximum Hurricane (PMH) were developed for a critical hurricane track affecting the Chesapeake Bay. The Probable Maximum Storm Surge (PMSS) due to the PMH was modeled using the industry standard software, and results were compared to results using an empirical method. The characteristics of the PMH, including wind speed, forward speed, and central pressure were developed using guidance from the National Oceanic and Atmospheric Administration (NOAA). The track and parameters of the PMH were used as inputs into the Sea, Lake, and Overland Surges from Hurricanes (SLOSH) software developed by NOAA. Antecedent water conditions were also evaluated. Together with the storm surge height predicted by SLOSH, a PMSS height was determined. The PMSS at the location of interest was also calculated using an empirical method. This method was developed by the United States Army Corps of Engineers (USACE) specifically for the Chesapeake Bay. The peak PMSS water surface elevation modeled by the SLOSH software was 13.1 ft above the antecedent water level. This was significantly lower than the PMSS elevation predicted by the empirical method. (Abstract ID 10466)

INFLUENCE OF KEY PARAMETERS ON PROCESSES ASSOCIATED WITH THE OXYGEN MINIMUM ZONE IN THE UPWELLING OFF NAMIBIA USING A 3-D MODEL

As regions of high primary production being often associated to Oxygen Minimum Zones (OMZs), Eastern Boundary Upwelling Systems (EBUS) represent regions of interest for the oceanic nitrogen and oxygen cycles. Indeed, losses of nitrogen (denitrification and anammox processes and nitrous oxide (N2O) emissions to the atmosphere) take place in oxygen depleted environments like EBUS, and decrease the role of nitrogen source of these regions. In the present study, a 3-D coupled physical/biogeochemical (ROMS/BIOS/BUS) model, already validated in the Namibian sub-system of the Benguela Upwelling System, is used. The nitrogen transfer has been investigated in the Namibian upwelling system using this coupled model, especially between 22°S and 24°S where the OMZ is well developed (< 0.5 mlO2/l). In this study, we performed a sensitivity analysis of the values of parameters associated with specific processes of the OMZs (denitrification/nitrification, nitrous oxide fluxes, anammox process, O2/N2O fluxes at the water-sediment interface) on nitrogen transfers in this system in order to know the most sensitive key parameters. For example, the anamnose rates between 0.01 and 0.45 d−1 are associated with nitrogen loss between 0.02 and 0.27 mmolN/m2 d−1 off Namibia. (Abstract ID 12943)

LINKAGE BETWEEN MARSH-DERIVED DISSOLVED ORGANIC CARBON (DOC) AND ECOSYSTEMS IN A NEARBY BAY AND THE COASTAL OCEAN.

We examined the contribution of DOC from a coastal marsh in Louisiana to the adjacent bay and coastal ocean in the northern Gulf of Mexico. Tidal flooding and relaxation cycles transported marsh-derived DOC into nearby open waters. The open water near the marsh edge was net heterotrophic on 97% of our study days. Twenty km offshore, bay water was net heterotrophic on 61% of the days studied but less strongly so than at the marsh edge. Concentrations of DOC at the marsh edge were, on average, twice as high as concentrations in the bay. Water temperature appeared to be the predominant source of variability in Net Ecosystem Metabolism on a seasonal time scale but variability of both respiration and primary production was high on shorter time scales associated with wind and light (cloudiness). Further transport out of the bay into the coastal ocean is indicated by a separate, previously published.
The concept of Redfield Ratios, or the ocean's nutrient stoichiometry has been fundamental to understanding the ocean biogeochemistry, reflecting the balance of elements between organisms and the chemical environment and thereby modulating to a large extent the metabolic status of an ecosystem as well as the ecosystem structure. This presentation will provide two case studies, one in the western South China Sea (WSCS) under the influence of meso-scale eddies and another in the northern South China Sea (NSCS) under the influence of both river plume and coastal upwelling. In responding to development of meso-scale eddies in the WSCS, we observed highly variable DIN (total inorganic nitrogen):DIP (reactive soluble phosphorus) molar ratios in the seawater fluctuating up to 44 in the upper 100 m water column. In the coastal upwelling zone and deep chlorophyll maximum layer of the NSCS, the DIN:DIP consumption ratio was 16.2±2.9, which is the classic Redfield ratio. In contrast, soluble phosphorus) molar ratios in the seawater fluctuating up to 44 in the upper 100 m water column. In the coastal upwelling zone and deep chlorophyll maximum layer of the NSCS, the DIN:DIP consumption ratio was 16.2±2.9, which is the classic Redfield ratio. In contrast, the river plume this ratio was 48±9.9. Possible mechanisms controlling the difference in nutrient consumption ratios in different physical and biogeochemical settings will be reasoned. (Abstract ID 10296)

The enhanced biological productivity in vicinity of islands is long known as Island Mass Effect (IME). IME is associated with flow perturbations by islands, and corresponding upwelling and vertical mixing supply nutrient rich deep water to the nutrient depleted surface euphotic layer and result in phytoplankton blooms. There have been numerous studies on IME and island wakes; however, due to the complexities of the wake dynamics, quantitative understandings of the vertical water exchange associated with oceanic islands and resulting IME are still lacking. Previously, we estimated upwelling speed of 0.01 m/s from the surface divergence observed by ADCP survey in a vicinity of a small island (D=5 km) in the Kuroshio current with horizontal flow speed of 0.1 m/s. In this study we investigate the upwelling associated with island wakes by using idealistic model experiments and theoretical analysis to explain how small islands induce strong upwelling in strong geostrophic currents. (Abstract ID 11498)

PLANKTON DYNAMICS FOLLOWING THE BP OIL SPILL

Human activity has impacted the Gulf of Mexico ecosystem for decades. The 2010 Deepwater Horizon Oil spill, however, was unprecedented for the volume of oil released, contamination by dispersant, and the oceanic depths over which this occurred. In addition to surface plumes of oil, subsurface plumes were documented to the southwest and northeast of the wellhead. Here we report the results of eight cruises to investigate plankton dynamics in the NE Gulf of Mexico, a region impacted by oil, and four cruises to the west shelf, a region relatively unimpacted by oil. Phytoplankton were collected for biomass, community composition, and assessed for photosynthetic inhibition. Zooplankton abundance and distribution was assessed using bongo tows and the SIPPER imaging system. Phytoplankton showed a reduced photosynthetic capacity in near-surface waters during August compared to following months. During May, zooplankton concentrations were reduced and detrital particles enhanced at stations closest to the wellhead. Maximum detritus concentrations occurred during August, within a month of capping the wellhead. Oiled detritus could have contributed to the flux of oil to the seafloor. (Abstract ID 12630)

THE OCEAN CARBON AND BIOGEOCHEMISTRY PROGRAM: BUILDING A COMMUNITY FROM THE BOTTOM UP

The Ocean Carbon and Biogeochemistry (OCB) Program and its Scientific Steering Committee (SSC) were created by NSF, NASA, and NOAA in 2006 to promote, plan, and coordinate collaborative, multidisciplinary research opportunities on marine biogeochemical cycling and ecosystem processes within the U.S. and with international partners. OCB focuses on the ocean’s role as a component of the global Earth system, bringing together research in biology, chemistry, and physics to advance our understanding of marine ecosystems and biogeochemical cycling. The OCB model is based on a community-driven set of research priorities and bottom-up implementation measures. The OCB Project Office, based at the Woods Hole Oceanographic Institution, plays multiple support roles, including coordination of scientific opportunities within the OCB community and with other U.S. and international programs; communication via websites, newsletters, and email lists; organization of workshops and activities; scientific and logistical support of its SSC and subcommittees; and development and dissemination of education and outreach materials. Here we provide an overview of OCB, including programmatic structure and current scientific foci, and report on key outcomes and challenges of recent activities. (Abstract ID 12890)

DEVELOPING SHELF-WIDE ESTIMATES OF BOTTOM STRESS FOR THE U.S. EAST COAST AND GULF OF MEXICO USING THE SWAN NUMERICAL WAVE MODEL

Ocean waves induce orbital motion that at shallow enough water depths results in a shear stress on the sea floor. Bottom wave stress depends on the strength and variability of local and regional wind forcing; wind wave and swell formation and propagation; and depth. Previous work has shown regional relationships between bottom stress and surface sediment texture in the Middle Atlantic Bight. Here we present wave stress data for the entire U.S. Atlantic and Gulf of Mexico continental shelf for the period April 2010-April 2011 on a 5-km grid calculated using the Simulating Waves Nearshore (SWAN) numerical wave model. Modeled bottom wave stress is validated against values calculated from ocean buoy wave spectra. Stress estimates are cross-correlated with wind stress forcing to determine where the waves that dominate regional stress generation are formed. Bottom stress depends strongly on spectral shape and the energy in longer periods, and model results are sensitive to directional resolution and seabed boundary conditions even at distances of hundreds of kilometers. VARIABILITY OF THE ATLANTIC MERIDIONAL OVERTURNING CIRCULATION IN CCSM4

Atlantic meridional overturning circulation (AMOC) variability is documented in the Community Climate System Model version 4 (CCSM4) pre-industrial control simulation. AMOC shows a broad spectrum of low frequency variability covering the 50-200 year range, contrasting sharply with the multi-decadal variability seen in the 20th century resolution CCSM3 present-day control simulation. Furthermore, the amplitude of variability is much reduced in CCSM4 compared to that of CCSM3. Parameterized eddy fluxes play a crucial role in the creation of salinity anomalies that dominate density anomalies in the Labrador Sea and influence AMOC. High Nordic Sea densities do not necessarily lead to increased overflow transports, because the overflow physics is governed by source and interior region density differences. Increased overflow transports do not lead to a higher AMOC, either. This has important implications for decadal prediction studies. Although the results suggest only weak direct impacts of the North Atlantic Oscillation (NAO) on AMOC variability, we speculate that NAO plays a role through setting the surface flux anomalies in the Labrador Sea and affecting the subpolar gyre circulation strength. ASSESSMENT OF SST ANALYSES IN SUPPORT OF OCEAN FORECASTING AT THE NOAA OCEAN PREDICTION CENTER

Forecasters at the NOAA Ocean Prediction Center (OPC) have several SST analyses available within their operational workstations including the NOAA Real Time Global SST (RTG_SST), the new RTG_SST with AMSR-E (NOMAA Optimum Interpolation Daily SST (OISST), the NOAA/ NESDIS Blended GOES SST, and the in-house 3-day composite GOES SST. The new RTG_SST incorporates observations from AMSR-E (Advanced Microwave Scanning Radiometer) along with AVHRR (Advanced Very High Resolution Radiometer) retrievals. Inclusion of information from these instruments gives forecasters an improved and timely awareness of ocean thermal features such as fronts and eddies during the winter storm season. This paper will compare the various SST analyses available to OPC forecasters and provide statistics of the comparisons. Examples of the use of SST to improve weather prediction over the Atlantic and Pacific will be given. (Abstract ID 10315)

CIRCULATION DYNAMICS OF THE CENTRAL EASTERN BERING SEA SHELF

We present analyses of a moored current meter array deployed between July 2008 and July 2010 on the eastern central Bering Sea shelf, a shallow shelf influenced by strong tidal forcing, strong (weak) winds in winter (summer), seasonal sea ice and strong summer stratification. Subtidal, vertically-integrated equations of motion show that the cross-shelf balance is geostrophic to first order. In the along-shelf direction, the pressure gradient and Coriolis terms also dominate, but local accelerations, wind stress and bottom friction account for up to 40% of the typical momentum balance, with the wind stress alone representing 5-20%, depending on the season and local water depth. Additionally, the wind stress contributes to the sea surface slope through Ekman divergence, and the resultant changes in sea surface topography significantly affect the flow, both in magnitude and direction. The varying coastline orientation induces along-shore current variations that complicate the flow field required to maintain mass continuity. Low frequency flows (< ¼ cpd) are coherent over distances exceeding 200 km, allowing us to compute shelf fluxing rates that vary seasonally and inter-annually. (Abstract ID 12355)

HIGH-FREQUENCY VERTICAL VELOCITIES IN THE DEEP OCEAN
Based on realistic numerical simulations of the primitive equations, we present two ways of generating strong high-frequency vertical velocities in the deep ocean. The first mechanism involves forcing by the wind. Interactions between the resulting inertial oscillations and mesoscale eddies generate strong vertical velocities both in subsurface and in depth, with values of the order of 100 m/s. The second mechanism does not require wind forcing, but a strongly turbulent, surface-intensified balanced motion. In this context, spontaneous emission of inertia-gravity waves takes place, that is mainly seen on the vertical velocity in depth where it reaches values of 10 m/s, of the same order as the balanced velocity. In both cases, the deep vertical velocity appears to be an excellent filter through which one can understand the physics of otherwise surface-intensified phenomenons. (Abstract ID 12555)

A GENE-BASED INDICATOR OF ION LIMITATION IN THE DIATOM THALASSIOSIRA OCEANICA

Diatoms are abundant primary producers and key players in marine nutrient cycling. In several oceanic regions, diatoms are iron limited due to low atmospheric inputs. Under these conditions, many phytoplankton replace ferredoxin, an iron-rich photosynthetic electron transport protein, with the iron-free protein flavodoxin. Thalassiosira oceanica, a diatom isolated in the open ocean, has three flavodoxin genes. We determined the expression profiles of all flavodoxin copies and ferredoxin in laboratory cultures of T. oceanica grown in iron limiting conditions under continuous and cycling light. Quantitative RNA expression analysis confirmed that one of the T. oceanica flavodoxin copies was sensitive to iron; its expression was induced 1000- or 3000-fold in iron limited cells depending on light conditions. The expression of the two other flavodoxin copies and ferredoxin did not change significantly under the experimental conditions. We are analyzing the expression of flavodoxin in field samples collected from Northeast Pacific ocean where we have previously identified T. oceanica in diatom populations to determine whether flavodoxin expression can be used as a field-based indicator of Fe status in wild T. oceanica populations. LEARNING PROBABILISTIC ORGANISM ABUNDANCE MODELS THROUGH INTELLIGENT WATER-SAMPLE ACQUISITION BY AUVs

Marine scientists are developing models that predict organism abundance (e.g. Pseudo-nitzschia) from environmental parameters that can be measured in-situ (e.g. temperature, salinity, etc). Learning such models requires molecular and morphological analysis of physically acquired water samples, along with concurrent measurements of environmental parameters. Water samples are usually collected manually from piers and ships, resulting in sampling bias that can impact model skill. To address this issue, we are developing adaptive sampling algorithms for AUVs equipped with water collection systems that can be triggered by onboard automation software. We exploit current methods in statistical machine learning to learn a non-parametric probabilistic model that allows us to predict organism abundance at unobserved geographic locations in a region of interest, using measurements of environmental parameters gathered during a pilot AUV survey. The uncertainty in the predicted organism abundance is used to compute a sampling policy that the AUV can use for future water-sample collection. We present results of our analysis on historical data gathered in Monterey Bay, and demonstrate the utility of our approach in using latest AUV technologies to learn organism abundance models. THE EVOLUTION OF PATCH OF THE NORTH ATLANTIC BLOOM

An array of four Seagliders surveying around a drifting Lagrangian float, supplemented by ship observations and occasional ocean color images was used to map thestraining and blooming of a patch of salty water advected from the North Atlantic Current into the Iceocean Basin. Optical sensors measured chlorophyll and POC; ship based imaging and flood cytommetry measured the community composition. Increased light and shallowing mixed layers caused a diatom bloom, terminated by salticule exhausting and with efficient export. However, the timing and intensity of the bloom varied by up to 3 weeks due to water mass and eddy variations resulting in a patchy bloom. Mapping revealed a detailed space-time picture for one such water mass; its initial blooming is suppressed by deep mixed layers; eddy stirring then fragments it into successively smaller filaments; one such 10 km x 20 km patch of high chlorophyll and POC blooms for about a week and disappears when its salticule became exhausted. These observations demonstrate combinations of autonomous and shipboard platforms and sensors can be used to make detailed mechanistic observations of biogeochemical processes. (Abstract ID 9576)

RADIATION BALANCE INFORMATION LEVELS FROM THE FUKUSHIMA DAICHI NUCLEAR DISASTER IN THE ALEUTIAN ISLANDS AND WESTERN COASTAL REGIONS OF ALASKA

Air parcels from the Fukushima Daichi nuclear disaster crossed over the Aleutian Islands and other regions of Alaska within days of the accident. U.S. Environmental Protection Agency RadNet stations located in Alaska detected radionuclides in the air samples. However, outside of air sampling no other environmental sampling was done at that time. In the summer of 2011, during the Anchsirk Island Underground Nuclear Test Site environmental assessment, the Alaska Department of Environmental Conservation and the University of Fairbanks (UAF) School of Fisheries and Ocean Science collected terrestrial and marine samples. These samples and others are being analyzed for Cesium 134 and 137 and other radionuclides at UAF and Lawrence Livermore National Laboratory (LLNL). Results of this work will provide information on the magnitude of the Fukushima fallout release in western Alaska coastal regions providing input into biological uptake models, and help test predictive models of atmospheric fallout deposition. SUPPORTING GULF OF MEXICO ECOSYSTEM RESTORATION: ISSUES AND CHALLENGES IDENTIFIED BY THE GULF COAST ECOSYSTEM RESTORATION TASK FORCE SCIENCE TEAM

The Gulf Coast Ecosystem Restoration Task Force (GCERTF) was established by Executive Order 13554 to develop a holistic, science-based Ecosystem Restoration Strategy for the Gulf of Mexico (GoM). As part of this effort, a Science Coordination Team (SCT) was formed to provide scientific input to the development of the Strategy. The SCT consisted of over seventy scientists from the state and federal GCERTF Member agencies. Starting with the ecosystem restoration goals described in “America’s Gulf Coast: A Long-term Recovery Plan after the Deepwater Horizon Oil Spill,” the SCT described current conditions in the Gulf, from inland watersheds to the offshore waters. Using this information, the team identified scientific gaps in understanding and high-level activities, with associated performance indicators, necessary to accomplish the goals of GCERTF. The team also identified the monitoring, modeling, and research essential to support restoration actions. The overall scientific assessment reveals that, Gulf-wide, the ecosystem continues to suffer from extensive degradation, and that integrated, science-based restoration initiatives, backed by a robust adaptive management framework, are necessary to develop a healthy, resilient, and sustainable GoM ecosystem. ZONAL JETS AND ENERGY CASCADES IN THE BAROCLINIC DOUBLE GYRE PROBLEM

We consider the baroclinic double gyre problem over a range of forcing and dissipation parameters. Zonal jet-like features appear over a wide range of parameters, and are clearly evident both in time-averaged and in instantaneous fields. Energy fluxes associated with various terms (beta, nonlinear, forcing, etc) are also described in detail. In the weakly nonlinear regime, the jets are seen to propagate meridionally. The barotropic mode shows a “double cascade”. That is, over a range of wavenumbers the inverse cascade associated with the barotropic nonlinear self-interaction term is nearly compensated for by an enhanced forward energy cascade associated with the beta term. This is markedly different from quasigeostrophic beta-plane turbulence in a doubly periodic setting, where the barotropic mode exhibits an
inverse cascade from near the Rossby radius to a scale related to the Rhines scale. Here, there is no net cascade. Instead, there is a cycling of barotropic energy with nonlinear effects driving it upscale, and the beta term bringing it back. (Abstract ID 11558)

DYNAMICS OF A MAJOR OUTLET GLACIER FJORD SYSTEM: CIRCULATION AND VARIABILITY IN SERMILIK FJORD, SE GREENLAND

Recent evidence points to the ocean as a trigger for the increased mass loss from the Greenland Ice Sheet. This hypothesis is supported by observations showing that relatively warm, submeltwater waters are present in Greenland's major glacial fjords, which act as conduits between the subpolar ocean and the ice sheet. However, the dynamics that control the circulation within these fjords is not well understood. The presence of stratification, absence of sill, and the deep, narrow geometry of the fjords complicate the use of classic fjord theory. Here, we present observations from Sermilik Fjord, in southeast Greenland, and identify the main modes of variability in velocity and hydrography from shipboard and moored instrumentation. We show that the fjord circulation is controlled via changes in the coastal current at the mouth of the fjord, but that internal modes of variability inside the fjord might play a significant role in mixing. We discuss the implications of this variability and how this modifies the fjords' dynamics. (Abstract ID 10066)

OCEAN NETWORKS CANADA OBSERVATORY: BRINGING THE MYSTERIOUS DEEP-SEA TO SHORE-BASED AUDIENCES THROUGH SOCIAL MEDIA, REAL-TIME DATA AND EDUCATION

Ocean Networks Canada Observatory (ONC), comprised of VENUS and NEPTUNE Canada underwater cabled networks, supports transformative science in coastal and deep sea ecosystems. The networks collect data in four interest areas: ocean health, energy resources; natural hazards; and marine conservation, and stream it online in real-time. This data allows researchers to begin to understand how the ocean works to sustain life on Earth. ONC uses education and communication as its primary strategies to engage its main audiences, the public, students, educators and scientists, with this important research. ONC utilizes social media outlets and an active website, specializing in live video streaming with its “SeaTube” tool, to successfully peak its audiences’ interests. For example, ONC’s online “Pig” video, which investigated underwater decomposition rates, went viral after a surprising shower of shrimp ripped the “victim” to shreds. ONC would like to explore Live Video Conferencing between school classes and researchers aboard NEPTUNE Canada and VENUS cruises. ONC also wishes to involve users with Digital Fishers, a crowd sourcing tool, and other like tools to allow them to contribute directly to ocean science. (Abstract ID 11530)

TOWARDS UNDERSTANDING PARTICLE SIZE DISTRIBUTIONS DERIVED FROM LASER DIFFRACTION

The use of laser diffraction is common practice for the determination of an in-situ particle size distribution. This method is adopted by the LISST-100 range of instruments (Sequua Scientific Inc.) and relies on Mie Theory; or an alternative algorithm, to infer a particle size and concentration from a measure of scattered light. However, these predictions have a number of restrictions, for example, Mie Theory assumes spherical particles of a known refractive index, and tested alternative algorithms do not cover the full range of particle sizes or shapes found within the marine environment. To assess the performance of the laser diffraction technique when measuring natural suspensions, we have simultaneously deployed a LISST-100X with a high-resolution holographic camera at a range of coastal environments around the UK, when measuring natural suspensions, we have simultaneously deployed a LISST-100X with a high-resolution holographic camera at a range of coastal environments around the UK, along with observations from specially constructed laboratory instrumentation. We observe substantial differences between the number distributions inferred by the instruments. To understand the causes of the differences observed, we present a novel approach for the multi-scale representation of particle size and assess the response of the LISST-100 to particles larger than the instrument range size. LUCKY PERSPECTIVE IMAGER FOR THE COASTAL OCEAN (HICO): OVERVIEW AND COASTAL OCEAN APPLICATIONS

The Hyperspectral Imager for the Coastal Ocean (HICO) is the first spaceborne imaging spectrometer designed to sample the coastal ocean. HICO samples selected coastal regions at 95 m with full spectral coverage (87 channels covering 400 to 900 nm) and a high signal-to-noise ratio to resolve the complexity of the coastal ocean. HICO has been operating on the International Space Station since October 2009 and collected over 4000 scenes. Here we give a brief overview of HICO and the validation of coastal ocean products. We give examples of HICO data applications including, shallow ocean environments, river plumes and harmful algal blooms. (Abstract ID 10049)

FRESHWATER Inputs AND COASTAL PRODUCTIVITY IN THE PACIFIC NORTHWEST

The coastal ocean plays a key role in global biogeochemical cycles. In the Pacific Northwest, the coastal waters are strongly influenced by freshwater inputs from the Strait of Juan de Fuca (fed by the Fraser and Puget Sound rivers) and the Columbia River. These rivers act as a conduit for land-derived nutrients and as a facilitator for entraining ocean-derived nutrients into the coastal euphotic zone. We present results from a four-box (NPFD) model of planktonic nutrient cycling coupled to a high-resolution circulation model of the Washington and Oregon coasts. Comparison of model results to physical and biological data from two recently completed observational studies indicates that the model is successfully reproducing nutrient and phytoplankton fields in the coastal Pacific Northwest. We examine a suite of numerical simulations of year 2005, comparing a base case with realistic bathymetry and forcing to three special cases: 1. with no Columbia River flow, 2. with no Fraser or Puget Sound river flow, and 3. with no Salish Sea, to examine the role of freshwater input and estuarine exchange on regional patterns of phytoplankton biomass and productivity. LOCAL OCEANIC THERMAL RESPONSE TO ATMOSPHERIC FORCING: THE GULF STREAM REGION

The dominance of the Gulf Stream (GS) in the local heat balance is observed in an hourly 14-month record of unprecedented surface mooring measurements from November 2005 to January 2007. Instrumentation on the buoy provided a high quality record of air-sea exchanges of momentum, heat, and freshwater flux; and oceanographic sensors recorded the upper ocean variability in the upper 600 m. The mooring was at times south of the GS and at other times north of the GS. Our intent is to isolate the local oceanic response to the atmosphere from the advective variability of the GS. A one-dimensional heat budget analysis indicates that the impact of atmospheric forcing on the heat budget is one order of magnitude larger than that associated with atmospheric forcing when south of the GS and on the same order of magnitude as the atmospheric forcing when north of the GS. Through an EOF analysis, the impact of GS and atmospheric forcing are decomposed, allowing the local linear local oceanic thermal response to be isolated. This linear air-sea interaction is particularly prominent during the periods of active cold air outbreaks and sustained heating. Case studies of the summer and winter oceanic response to atmospheric forcing in the GS region. (Abstract ID 11333)

INVESTIGATING THE ROLE OF BAROCLINIC FLOWS IN TIDAL CHANNEL MORPHOLOGY AND SEDIMENT TRANSPORT

A dense array of Acoustic Doppler Profilers and Conductivity-Temperature gauges were used to measure flow near the curved edge of a shallow (<1 m low tide, >3 m high tide) tidal channel in the Skagit River tidal flats. A simple sediment transport formula [Meyer-Peter and Muller (1948)] applied to measured near-bed velocities predicts peaks of seaward sediment transport as the tidal flats are drained late in ebb tide. During this time, a transition was observed from strongly depth-dependent flow towards more depth-uniform flow. We examine the causes of this transition, and its consequences for sediment transport. We investigate the possible influences of channel curvature and stratification on the observed flow. (Abstract ID 10035)

THE OFFSHORE NORTHEASTERN CHUKCHI SEA: A COMPLEX HIGH-LATITUDE ECOSYSTEM

In 2008–2010, we conducted an interdisciplinary ecological study (Chukchi Sea Environmental Studies Program; funded by ConocoPhillips, Shell, and Statoil) in and near three proposed exploratory oil and gas prospects in the offshore northeastern Chukchi Sea during the open-water season. Some aspects of this ecosystem function as a classical pelagic–benthic dichotomy, whereas others suggest unusual ecosystem-level attributes. The Klondike study area functions as a pelagic system, whereas the Burger study area is primarily a benthic system; the Statoil study area has both pelagic and benthic attributes. Klondike has lower benthic abundance and biomass and more oceanic zooplankton, fishes, zooplankton-feeding seabirds, and pelagic-feeding seals than does Burger, which has benthic communities with high abundance and biomass, primarily neritic zooplankton, and more benthic-feeding marine mammals than Klondike. Statoil has characteristics of both ecosystems. Various water masses impinge onto all study areas seasonally and interannually, and patterns of sea-ice retreat vary interannually, leading to pelagic blooms in some years but within-ice production in others. These variations affect some of this pelagic–benthic dichotomy, and some aspects of this ecosystem suggest unusual structure. (Abstract ID 9593)

MARINE ECOSYSTEMS IN A HIGH-CO2 WORLD: BALANCING BETWEEN SINCERE SCIENTIFIC CONCERN AND OVERSTATEMENT THAT MAY INCITE CLIMATE SCEPTICISM

Invading anthropogenic CO2 into the oceans has long been known to cause shifts in ocean chemistry. Projected doubling of dissolved CO2 in surface waters is accompanied by ~15% increase of major bicarbonate (HCO3−) and ~50% decrease of carbonate (CO3−). These shifts in the seawater buffer decrease the minor hydroxide (OH−). Time series measurements confirm this. Eventually this shift arrives at the deep seafloor where enhanced dissolution of fossil CaCO3 deposits is long recognized due to carbonate undersaturation. Conceivable but not proven is that this dissolution will be enhanced by the resulting increase in pH of the water. In the long run, increased contribution of subtropical waters in the Iceland Basin and to the large increase of the winter convection, to an increased contribution of subtropical waters in the Iceland Basin and to the large increase of the

oriGin, formation and variability of the sUbPolar mode wAter observed over the reyKjanes ridGes

Using a 1/4 global simulation and a Lagrangian tool, we investigate the origin, formation and variability of the Reykjanes Ridge Mode Water (RMW) over 1966–2004. The source waters of the RMW originate from the Labrador Current and the Gulf Stream and are advected to the Reykjanes Ridge by the branches of the North-Atlantic Current. The RMW acquires its properties in winter in the Iceland Basin when its source waters enter the mixed layer. The variability of the SPMW is driven by two mechanisms. On a decadal time scale, changes in the intensity of the winter convection condition the properties of the subpolar waters. On a decadal time scale, changes in the intensity of the winter convection condition the properties of the subpolar waters. On a decadal time scale, changes in the intensity of the winter convection condition the properties of the subpolar waters. On a decadal time scale, changes in the intensity of the winter convection condition the properties of the subpolar waters. PACIOOS – “BUILD IT AND THEY WILL USE IT”

PACIOOS, last and biggest of the eleven IOOS Regional Associations, has been operational since 2008. Various water quality components including AUVs, buoys, nearshore sensors, and a seabed observatory have been deployed and have collected millions of data points at intervals ranging from seconds to hours, providing unprecedented coverage of the coastal ocean at an estimated cost of ~$370/day. This network not only provides cost benefits over ships but enables both science and public reaction. PACIOOS assets provide 24-hour near real-time coverage of the coastal ocean in weather that might preclude vessel operations or satellite observations. In this presentation we will illustrate data that have been recorded by PACIOOS assets, challenges in operating and maintaining the system, as well as describe the potential science and the agency and public benefits these data enable. The near-real time data from PACIOOS describes extant and recent past coastal conditions and the 24/7 coverage allows impacts of storms, spills and wave events on the coastal ocean to be quickly identified and appropriate action to be taken to be defended the health of Hawaiians residents and visitors. BASIN-WIDE SYNCHRONOUS FORMATION AND REDOX-CONTROLLED PRESERVATION OF MEDITERRANEAN SAPROPELS 1

Preservation-related deposition of Mediterranean sapropels are associated with humid climate conditions. The last of such humid periods occurred from 10 to 5 ky ago, simultaneously with the sustained wet period in the cirmadian Mediterranean area. The end of this period coincides with a high MnO₂ peak in all 30 studied cores and concurs with an abrupt re-ventilation event at 5.7 ky 14C. As a consequence of increased fresh water (monsoon) input during that humid period, the most recent saprope 1 formed synchronously between 9.8 and 5.7 ky 14C BP at all water depths greater than a few 100m. Surface waters had a reduced salinity and concomitantly the deep (< 1.8 km) eastern Mediterranean Sea was devoid of oxygen during 4,000 years of formation (De Lange et al., 2008). This has resulted in a differential basin-wide preservation associated to water depth, as a result of different ventilation/climate-related redox conditions above and below 1.8 km. Climate-induced stratification of the ocean may thus contribute to enhanced preservation of organic matter, i.e. to formation of sapropels (and potentially black shales). De Lange e.a., 2008. Nature Geo 1, 600-601. (Abstract ID 11315)

SUBMARINE CANYONS AS HOTSPOT OF BENTHIC BIODIVERSITY: EFFECTS OF LOCAL VS. LANDSCAPE HABITAT HETEROGENEITY.

The mapping of biodiversity on continental margins (CM) on landscape scales relevant to marine spatial planning and conservation is increasingly important. Submarine canyons are widespread topographic features on continental and island margins that enhance benthic biomass across oceanic provinces, latitude or primary production regimes. However, it remains unclear whether canyons enhance faunal biodiversity on landscape scales relevant to marine protected area design. Furthermore, it is not known which physical attributes and heterogeneity metrics can provide good surrogates for large-scale mapping of canyon benthic biodiversity. We employ multivariate multiple regression models to evaluate sediment and topographic heterogeneity, canyon-curvature profiles, and overall water mass variability as potential drivers of macrobenthic community structure and species richness in 6 canyons of the Hawaiian archipelago. We find that variables related to habitat heterogeneity at medium (0.13 km²) and large (15-33 km²) spatial scales such as slope, backscatter reflectivity and canyon curvature profiles, often explain a greater proportion of variation in benthic biomss. Sample depth and distance from shore are also important, implicating food supply as a major predictor of canyon biodiversity. (Abstract ID 12677)

SESSION OVERVIEW: ADVANCES IN COASTAL OCEAN MODELING, ANALYSIS, AND PREDICTION

This overview will summarize the major topics addressed in this session, and will connect coastal ocean modelling research with ongoing ocean prediction activities within GODAE OceanView (GOV). Downscaling and extending predictability in coastal and shelf seas are two of the objectives of the GOV initiative through its international Coastal Ocean and Shelf Seas Task Team (COSS-TT). The main goal of the COSS-TT is to work towards the provision of a sound scientific basis for sustainable multidisciplinary downscaling and forecasting activities in the world coastal oceans. The main objective of this session is to provide a forum for multi-scale hydrodynamic modeling and observational studies that aim toward scientific validation, prediction and operational applications of numerical models in coastal and shelf seas, leading to new understanding of multiscale, interdisciplinary nonlinear ocean processes. Applications of nested models, such as the influence of physical processes on ecosystem dynamics and interdisciplinary coastal predictions are also addressed. The session promotes the discussion of methodologies that lead to reliable coastal forecasts (such as data assimilation, error analysis, influence of nesting, resolution and forcing), Observing System Simulation Experiments and the impact of sustainable, integrated modeling and observational networks that connect local, regional and global scales. (Abstract ID 9901)
the distribution of prey resources. Off Sri Lanka, the physical processes are complicated by a monsoonal regime with seasonally reversing currents and changing salinities. Using archived model results, satellite imagery and field data we attempt to understand the influence of oceanic processes on blue whale distribution in this area. During early 2011, whale sightings were consistently further offshore than in previous years. Results suggest that this is due to the anomalously high rainfall and associated freshwater input to the ocean, which may have displaced the krill aggregations on which the blue whales feed. The more saline offshore waters where whales were observed feeding are likely more favourable for krill aggregations. Here we show the influence of the freshwater output from the Bay of Bengal and local rivers on local physical processes and explain changes in whale distribution between 2011 and previous years. MODEL CALCULATIONS OF BUBBLE FRAGMENTATION IN BREAKING WAVES AND COMPARISON WITH LABORATORY DATA

During active breaking, whitecaps entrain dense plumes of bubbles in the near-surface ocean layer, ranging in size from 10% of micrometers to 10% of millimeters. Depending on their size, these bubbles persist in the water column from seconds to minutes and impact interface processes, such as air-sea gas transfer and primary marine aerosol production. Despite their importance, relatively little is known about the initial size distribution of these bubbles and its dependence on environmental factors, such as wind speed, the wave spectrum and surfactants. Bubble creation processes in breaking waves are known to be scale-dependent, with the large end of spectrum driven by fluid turbulence and bubble fragmentation. A physical model for bubble fragmentation in whitecaps is presented and compared with the distributions of bubbles observed in laboratory seawater waves. The role of surface tension in shaping the distribution will be discussed. (Abstract ID 12532)

THE BERING SEA ECOSYSTEM WORKSHOP - A MODEL FOR TRANSFORMING ECOSYSTEM SCIENCE INTO EDUCATIONAL RESOURCES

The North Pacific Research Board (NPRB) and partners COSEE-AK, ACOOS, ARCSS, and MBARI brought together teachers and scientists for professional development and the sharing of outcomes of the Bering Sea Project, a landmark integrated ecosystem study, in October 2011. Using the ecosystem study hypotheses as a guide, and with a focus on the use of data in the classroom, educators and researchers presented and learned from each other. Teachers and informal educators attended workshops and presented their projects and discussions. The model also gained insights into how to communicate with educators and students. Educational resources generated during the workshop were posted as a comprehensive Bering Sea Ecosystem Collection hosted through ARCUS' PolarTREC Learning Resources database at http://www.polartrec.org/collections/bering-sea-ecosystem.

INTRUSION OF ANTARCTIC MELT WATER AND ITS EFFECT ON UPPER OCEAN VARIABILITY IN THE SOUTHERN INDIAN OCEAN

The effect of intrusion of melt water on upper surface of the Indian sector of the Southern Ocean along the latitudinal section from 59S to 55S in the months of January and February for three years 1992, 2003 and 2007 have been studied using CTD, PEL and ARGO profiles. The temperature and salinity sections show an intrusion of cold water between depths 50m and 150m. Northward Ekman transport is seen in this region. The extent of intrusion is found to have a strong positive relation to the maximum ice edge in this sector: The presence of the Kerguelen plateau also affects the upper ocean behavior: The study of geostrophic velocity shows the presence of two- and cyclonic eddies between 58S to 57S and a cyclonic eddy at 57 S in 1992 and 2003. Whereas in 2007 the anticyclonic eddies almost disappear and the cyclonic eddies appear at around 56S, which may be due to more freshwater input due to sea ice melting. Thicker barrier layer is extended towards north in 2007 compared to other two years. This may be due to larger equator ward sea ice extent in 2007 compared to other years. (Abstract ID 9599)

AQUARIUS/SAC-D SATELLITE MISSION – US AND ARGENTINA WORKING TOGETHER TO UNDERSTAND OUR OCEANS

AquaSAC-D is a collaboration between NASA and Argentina’s space agency, Comisión Nacional de Actividades Espaciales (CONAE). On June 10 2011, the Argentine-built spacecraft, Satélite de Aplicaciones Científicas (SAC-D), carried several CONAE-sponsored science sensors into space, including those that measure sea ice concentration and sea surface temperature. The primary payload, NASA’s Aquarius instrument, began mapping global sea surface salinity in late August 2011 and has detected large-scale salinity distribution features clearly and with sharp contrast. Ocean-related data from AquaSAC-D are complementary, as are the US and Argentine approaches to education and public outreach (EPO) for this satellite mission. In the months leading up to the launch, close communication was vitally important, including international collaboration to develop key messages, create EPO products, coordinate media opportunities, and facilitate the broader impacts of the mission’s scientific goals. With new ocean data being collected, EPO staff in both countries are helping various communities to use Aquarius/SAC-D observations to better understand the interactions between global ocean circulation, the water cycle and Earth’s climate. In addition, more focused EPO activities address socio-economic applications such as fisheries management. (Abstract ID 9497)

USING LINEAR MIXED-EFFECTS (LME) MODELS TO DISTINGUISH BASELINE AND TROPHIC 15N ENRICHMENT: ENSO EFFECTS ON ZOOPLANKTON IN THE CALIFORNIA CURRENT

Applications of Compound-Specific Isotopic Analysis of amino acids (CSIA-AA) to ecological questions typically use one pair of AAs - phenylalanine and glutamic acid – to distinguish between baseline and trophic 15N enrichment. We developed a linear mixed-effect (LME) model that utilizes all AAs for such assessments. Data are clustered into three levels that reflect the hierarchical covariance, with fixed effects investigated for AA and treatment levels. We used this approach to test the hypothesis of baseline versus trophic 15N enrichment for two dominant planktonic crustaceans (Calanus pacificus and Clausocalanus pacificus) from the California Current Ecosystem during and after the 1998 ENSO. Using the traditional approach, phenylalanine, while visibly enriched in 15N during 1998 for all groups, was not statistically
different between years for C. pacificus females. The differences in δ15N values of glutamic acid and phenylalanine, a proxy for trophic enrichment, were not statistically different between years for C. pacificus. (Abstract ID 11766)

A COMPARISON OF TOPOGRAPHY-CATALYZED DIAPYCNAL MIXING PARAMETERIZATIONS TO OBSERVATIONS

Flow-topography interactions energize the internal wave field, often leading to enhanced turbulence and diapycnal mixing. Numerous observational studies reflect this, inferring enhanced mixing over rough topography and weak mixing elsewhere. OGCM studies using spatially varying mixing parameterizations clearly demonstrate the sensitivity of the ocean circulation to the heterogeneity of mixing. A few heterogeneous diapycnal mixing parameterizations using topographic roughness as a proxy for enhanced mixing are now in use. These remain rudimentary and have been subject to little validation. We here compare the tidal mixing parameterization by St. Laurent and co-authors and the Roughness Diffusivity Model (RDM) by DeCloeht and Luther to each other and observations ranging from microstructure surveys to basin-scale hydrographic inverse estimates. The parameterizations yield similar basin-averaged diffusivities but have dramatically different spatial distributions leading to different circulations in OGCMs. Both parameterizations are conservative compared to inverse estimates in mid-latitude basins and significantly underestimate diffusivities in the Northern Indian and Southern Oceans, suggesting that mixing processes other than the breaking of topography-catalyzed internal waves play an important role in setting the global spatial distribution of diapycnal mixing. (Abstract ID 12475)

SCHEDULING SENSORS FOR BIO-GEO-CHEMICAL PROFILING FLOATS

Teledyne Webb Research Apex floats are being used for bio-geo-chemical profiling measurements, using a Saphanti/WETlabs bio-optical sensor system. This requires different sets of sensors, as well as different sampling modes, to be used between different pressure ranges and at different times during the day. In addition, float behavior (such as ascent rate) must be controlled, depending on the pressure range. These requirements have been met using a novel approach to describing how the sensors and profiles behave. For example, sensors are grouped into sets, with properties such as data verbosity levels, and whether active-optic or radiometry-related measurements are to be included. Profiles are then divided into pressure ranges, with each sensor set being programmed separately within each pressure range. Finally, profiles can be updated remotely (via the Iridium satellite system), which is important when ocean properties to be measured change due to season or float location. This approach has been successfully tested using two floats, in three deployments near the BOUSSOLE site, France, in collaboration with the University of Maine. (Abstract ID 11465)

MARITIME SECURITY SUMMER RESEARCH: DIVERSITY INITIATIVES

The Center for Secure and Resilient Maritime Commerce (CSR), a Department of Homeland Security National Center of Excellence, aims to increase student interest and knowledge of the maritime domain, the marine transportation system and the sensor technologies used to secure our nation's ports, coastal borders, and remote and extreme islands, through a unique 8-week intensive STEM-based summer research program. The Summer Research Institute (SRI) engages a diverse group of undergraduate students from MSI, HBCU and other U.S. universities, in hands-on, multi-disciplinary research in collaboration with CSR researchers from Stevens Institute of Technology, Rutgers University, University of Puerto Rico, University of Miami, Monmouth University and MIT. The SRI has already been a stepping-stone for many students to pursue advanced academic study in maritime systems and career opportunities within the maritime homeland security domain. In the second year of the program, the number of minority participants increased through targeted recruitment and close partnerships with MSI and HBCU institutions. We will describe our strategy and our continued efforts to expand our outreach to under-represented populations. (Abstract ID 12102)

INORGANIC CARBON AND CALCIUM CARBONATE SATURATION STATES: CALCULATION FROM IN SITU PH AND PCO2 DATA

The oceans' uptake of anthropogenic CO2 is clearly to our benefit and understanding the processes that control the uptake is vitally important. There are also negative consequences to consider. Although the ocean inorganic carbon reservoir is huge, it has been measurably altered by the penetration of anthropogenic CO2 from the atmosphere resulting in acidification of the surface ocean. More inorganic carbon data in space and time will help improve predictive models and estimate the effects of acidification, e.g. on calcium carbonate saturation states. Here we discuss the pros and cons of using the only commercially-available inorganic carbon measurement systems, pH and pCO2, for quantifying the marine inorganic carbon system. Data from a number of coastal studies show that CaCO3 saturation can be accurately quantified and that the combined pH and pCO2 data are valuable for measurement quality control. However, errors in calculated dissolved inorganic carbon and total alkalinity can be large, due to temporal and spatial mismatches between data sets and the inherent error in the pH and pCO2 combination. (Abstract ID 11554)

ARCTIC OCEAN BOUNDARY CURRENTS IN THE ARCTIC CAP NOWCAST/FORECAST SYSTEM

The boundary currents of the Arctic Ocean are investigated using the Arctic Cap Nowcast/Forecast System (ACNFS). The ACNFS in the Arctic Ocean model being utilized by the Naval Oceanographic Office. It is a fully two-way coupled ocean-ice model utilizing the Hybrid Coordinate Ocean Model (HYCOM), coupled to the Los Alamos sea ice model (CICE). It is forced using the Fleet Numerical Meteorology and Oceanography Center's Navy Operational Global Atmospheric Prediction System (NOGAPS) atmospheric fields and assimilates remote sensing and in situ data. Examples of the validation, and an initial investigation of the boundary currents that are found in the model are presented. Given the general lack of data in the Arctic, in particular with respect to current measurements, the suitability of the model to investigate boundary currents is discussed. The use of operational models to investigate the ocean and the difficulties associated with it are also discussed. (Abstract ID 10415)

THE POPULATION ECOLOGY OF NON-INDIGENOUS ASCIDIANS ON THE SOUTH COAST OF NEWFOUNDLAND

We have recently discovered two non-indigenous ascidians, Botryllus schlosseri and Botrydiiodes violaceus, in several harbours on the south coast of Newfoundland. As neither species has been detected on the east or northeast coasts of the island, it appears that they are at the northern boundary of their range and limited by low temperature and a short productive season. Since both of these species are pests of aquaculture operations elsewhere, we designed an interdisciplinary research program focused on factors predicting invasion fitness and future spread. Our results are intended to inform zonal closure and mitigation decisions of government. The seasonal life cycle of B. schlosseri is being determined in Arnold’s Cove, including somatic growth and the rates and timing of asexual and sexual reproduction decisions of government. The seasonal life cycle of B. schlosseri is being determined in Arnold's Cove, including somatic growth and the rates and timing of asexual and sexual reproduction decisions of government. The seasonal life cycle of B. schlosseri is being determined in Arnold's Cove, including somatic growth and the rates and timing of asexual and sexual reproduction decisions of government. (Lowen oral presentation) and larval recruitment (companion Ma poster). Since mitigation is more effective if applied early in an invasion, TaqMan assays are being developed with the aim of being sufficiently sensitive to detect a single egg or larva (companion Applin poster). Gene sequence information will also be used to infer source populations of the Newfoundland invaders. (Abstract ID 10305)

ORGANIC/INORGANIC NUTRIENT CONTROL OF N2 FIXATION IN THE EASTERN TROPICAL SOUTH PACIFIC

N2 fixation has generally been studied in oligotrophic areas depleted in N, as N2 fixers are thought not to be competitive in N rich areas, or do not fix N2, which is a costly process in terms
of Fe quota and energy. In the Eastern Tropical South Pacific, incubation-based N2 fixation rates were measured both in surface and subsurface waters. Samples were collected along 10° & 20°S from nitrate-rich upwelling waters to highly oligotrophic conditions at 100°W, with euphotic zone nutrient amendment experiments (trace-metal clean conditions). These experiments indicate that nitrogen fixation was iron limited along 10°S, except in nearer-shore regions, where rates were limited by organic carbon availability. In the nutrient-replete subsurface, nitrogen fixation rates were highest in the core of the oxygen minimum zone (OMZ), and were significantly stimulated by additions of organic carbon at some stations. Volume-integrated rates of nitrogen fixation were higher in the OMZ, compared to the euphotic zone, in spite of ~10µM nitrate. These results will be discussed in the context of molecular analyses conducted targeting a marker gene for nitrogen fixation, nifH. (Abstract ID 10961)

DESIGNING THE ENTERPRISE ARCHITECTURE OF THE GREAT LAKES OBSERVING SYSTEM

The NOAA Great Lakes Environmental Research Laboratory (GLERL) and its partners (Great Lakes Observing System (GLOS), EPA-Great Lakes National Program Office and the United States Geological Survey) have recently developed the near-term design of a comprehensive observing enterprise that will serve as the next generation of the Great Lakes Observing System. An observing system enterprise begins with a detailed catalog of user needs within the Great Lakes, and proposes observations, sensing systems, and management and information structures that will best support those user needs. The enterprise will comprise: an array of data collecting systems, including satellites, aircraft, fixed platforms and buoys, drifters and floats, automated underwater vehicles, towed sensor arrays, and ships; telemetry; a data management and communications (DMAC) system, which stores and organizes the data for use in developing products and services; and the products (such as models) that support the user needs. This presentation describes the development of the design, focusing on the unique aspects of an observing system that functions at multiple scales (whole-basin, lake and regional) in the Great Lakes, and summarizes plans for implementation. (Abstract ID 12204)

UNDERSTANDING THE PLANETARY LIFE SUPPORT SYSTEM: NEXT-GENERATION SCIENCE IN THE OCEAN BASINS

Driven by solar and internal geothermal energy, the complex processes interacting within the global ocean constitute our planetary life-support system. New approaches to understanding this “oceanic modulator” are arising from submarine cabled networks, such as the one now under construction by the NSF Ocean Observatories Initiative, that provide electrical power and bandwidth to distributed sensors. Oceanographers are poised to benefit from a host of emerging technologies external to the ocean sciences, such as robotics, telecommunications, biotechnology, cloud computing, in situ chemical and genomic sensors, extraction of novel biochemical materials, digital imaging, nanotechnology, serious gaming, new visualization technologies, computational simulations and data assimilation, and seismo-acoustic tomography. More powerful than any one of these emerging technologies is the convergence of the ensemble. As rapidly evolving capabilities are integrated into sophisticated, remote, interactive operations throughout the ocean basins for decades, a new era of a human telepresence throughout our once “inaccessible” global ocean will be realized. Such capabilities are required to meet the immense environmental and societal challenges in the coming decades that can only be addressed through optimally informed international collaboration. INTER-ANNUAL ANALYSIS OF SURFACE TEMPERATURE, CHLOROPHYLL-A AND INHERENT OPTICAL PROPERTIES FROM SATELLITE OBSERVATIONS IN THE SW OF BUENOS AIRES (ARGENTINA)

The inner shelf of the southwest of Buenos Aires Province (Argentina) is a very complex natural system. It combines an heterogeneous bathymetry, the presence of an estuary and outflows of rivers, and a important input of energy produced by the tide and wind. A global study of diverse satellite products was made in order to obtain a dynamic regionalization of the study area. In addition the seasonal and inter-annual behavior of the sea surface temperature (sst), chlorophyll-a (chl-a) and inherent optical properties (IOPs) were analyzed and related to the hydrographic and climatological characteristics of the area. Nine years data of Moderate Resolution Imaging (MODIS) were processed in order to get the set product. In situ data obtained from oceanographic campaigns were used to validate the results on the set. Weakly and monthly composities of ten years of Sea Viewing Wide Field of View Sensor (SeaWiFS) were made in order to determine different regions based on Ocean Color derived chl-a and IOPs. Finally, the inter-annual and seasonal trends of the parameters were obtained with the Census X-11 method. (Abstract ID 11886)

IT’S COMPLICATED: VARYING TOPOGRAPHY AND THE ABYSSAL BOTTOM BOUNDARY LAYER

Physical oceanographers know the total amount of abyssal mixing and upwelling required to balance the deep-water formation, but we are still working to understand the mechanisms and locations—how and where it happens. From observational studies, we know that areas of rough topography are important and the hundreds of mid-ocean ridge canyons have particularly energetic mixing. Inspired by these observations, we studied diffusive boundary layers over varying topography using theoretical and numerical techniques. These boundary layers share many important properties with observed flows in abyssal canyons, like strong up-slope currents and acceleration near topographic sills. They also have a previously unidentified capacity to accelerate into non-linear overflows for a variety of oceanographically relevant shapes and sizes of topography. They also can force exchange of large volumes of fluid between the relatively unstratified boundary layer and the stratified far-field fluid, altering the stratification far from the boundary. In conclusion, these boundary layer processes may be a previously neglected source of a dynamically important amount of abyssal upwelling, profoundly affecting predictions of the basin-scale circulation. PREDATOR:PREY SIZE RELATIONSHIPS IN PELAGIC ECOSYSTEMS: TESTING THE 10:1 HYPOTHESIS WITH MESOZOOPLANKTON FROM THREE REGIONS

Size-based theories of energy flow in pelagic marine ecosystems, as well as numerous conceptual models, assume that predators and prey are linked, on average, by a body length ratio of 10:1. We tested this hypothesis using bulk N and Compound-Specific Isotope Analyses (CSIA) on zooplankton in the 2 to 5 mm size range collected from three biogeochemical systems: the California Current Ecosystem (CCE), the Costa Rica Dome (CRD) and the subtropical North Pacific (Stn. ALOHA). Bulk δ15N values reflect substantial regional differences in the dominant N cycling processes, which vary from N2 fixation (Stn. ALOHA) to denitrification (CRD). However, the slopes of bulk δ15N versus size suggest that a 10-fold size difference corresponds to ~1/4 of a trophic level, implying a mean predator:prey size ratio in natural systems ~100:1. CSA corrects for source N differences among regions and size classes, but does not markedly alter this conclusion. CSA assessments of trophic position versus size strongly overlap for the three regions. If these results are generalizable, energy transfer to higher trophic levels of ocean systems may be substantially more efficient than previously considered. (Abstract ID 11985)

WHERE HAVE ALL THE OYSTERS GONE: NATURAL AND ANTHROPOGENICALLY CAUSES FOR DRASTIC OYSTER REEF LOSSES IN GULF OF MEXICO ESTUARIES

In light of 85% loss global loss in oyster reefs, we consider examples from the Gulf of Mexico. Naples and Dollar Bays are small, connected bays in south Florida. Dollar Bay is a natural system with mangrove shorelines and a sandy bottom. Naples Bay, similar to Dollar Bay prior to 1940, is nearly completely bulkheaded, with extensive canals, has filled with +50 cm of sand and power line towers. Oyster reefs first started developing in Copano Bay (Texas) 6 ka, when sea level rise slowed and reefs began forming on fluvial terraces. By ~4.5 ka, 54% of the bay bottom contained oyster reef and shell. With additional sea level rise, the bay filled with mud, reducing reef distribution by 64%. (Abstract ID 10276)

IOPs. Finally, the inter-annual and seasonal trend of the parameters were obtained with the Census X-11 method. (Abstract ID 11886)
100-day timescales is being established based on sediment inventories of 234Th. Radiochemical constants over the four remaining stations. The relative mass flux reaching the seabed on change is being developed.

Benthic ecological processes along this transect exhibiting contrasting ice conditions, insight into the response of this important high-latitude environment to current and future climate change is being developed. By determining trends in biogeochemical tracers along the N/S transect as well as to document possible hiatuses in deposit feeding on the Antarctic Continental Shelf) established 5 stations along a 600 km N/S transect on the West Antarctic Peninsula Shelf. By determining trends in biogeochemical tracers and on 250 years by including an additional core from the same colony. (Abstract ID 10067)

We investigate nonenvironmental variability within and among coral colonies and evaluate the errors associated with sampling, chronology, and temperature reconstruction using cross-dated coral Sr/Ca records from five coral cores recovered from three Porites lutea colonies in New Caledonia (22°28.8′S, 166°27.9′E). Our results reveal that it is necessary to select sampling paths with corallites extending parallel to the slab surface along the apex of the corallite fan to achieve reproducible results. Cross-dated and optimally sampled coral Sr/Ca variations are coherent on subannual to centennial time scales and are reproducible for more than three centuries within analytical precision or 0.28°C. Chronology error for a multicentury reconstruction based on a single core varies between 2.5 to 3.8 years century^-1 compared to our multicore chronology. We find the monthly anomaly reconstruction error (1σ) for a single core is 0.95°C and 0.59°C for five intra- and intercolony cores. For interannual variability, the error is reduced by ~33% by including an additional colony, whereas the chronology error is reduced for reconstructions >250 years by including an additional core from the same colony. (Abstract ID 10067)

We describe and assess the accuracy and precision of a new methodology for estimating the temperature and salinity of water during the annual cycle at Mississippi Canyon 118. The carbonate-hydrate mound is the site of the Gulf of Mexico Hydrates Research Consortium’s seafloor observatory to investigate and monitor hydrographic, geophysical, geological, geochemical and biological processes of the hydrocarbon system, northern Gulf of Mexico. Seafloor morphology and geology have been characterized integrating high resolution swath bathymetry, acoustic imagery, seafloor video and multiple resolution seismic data with sediment, water column, and pore-water samples collected over a long period of observations (2002-2011). Outcropping hydrates, fluid-migration features and seafloor communities identified and described from numerous types of imagery have been mapped. These maps have been combined over time on the bathymetry/fault maps to produce a biotypes-seep map from which we have identified and differentiated types of seeps. Community complexity is used as a proxy for seep duration/age while specific community components are believed to reflect composition of seep fluids. Although preliminary, this approach represents a novel classification system for seafloor hydrocarbon seeps. (Abstract ID 9968)

Recent ocean observations demonstrate a general trend of warming of the Labrador Sea over the past two decades. The processes which contributed to the change of the Labrador Sea are related in a complex way to the recent variations in the large scale atmospheric circulation and response of the ocean to these variations. In this study we use an eddy-resolving ocean general circulation model of the Labrador Sea to simulate the ocean variability in the past 30 years. The variations in the deep and intermediate water masses formation, intensity of the mean circulation and energetics of mesoscale eddies are assessed. The model results show a strong interannual variability in the formation rate of the Labrador-Sea Water (LSW) during the studied period. There was a trend of decay of the volume of the newly formed LSW during all years of the past decade, with exception of 2008. This decay is concurrent with an increase of the inflow of Inirriging Water in the Eastern Labrador Sea. The energetics of the mesoscale processes during the past decade is studied and the dominant processes in the eddy energetics and their relation to the large scale circulation variability are discussed. (Abstract ID 12596)

The VENUS cabled network in the Strait of Georgia has been observing environmental variables continuously since 2008 in the Strait of Georgia off the mouths of the Fraser River in British Columbia, Canada, a high traffic area with ferries, container, oil and coal terminals, the main shipping lane between the Pacific Ocean and Vancouver Harbour, and an active salmon fishery. We are currently adding profiling gliders, ocean and met sensor packages on three main shipping routes of BC ferries, and a CODAR high frequency radar system that will monitor surface currents and waves. We plan to implement a high resolution assimilating ocean circulation model to provide operational ocean and environmental forecasts on time scales from hours to weeks, including an early warning system using NEPTUNE Canada observations from offshore for intrusions of low oxygen, low pH waters that have been implicated in mass mortality of cultured scallop larvae in the northern Strait. The challenge will be to develop an integrated representation of these disparate observations and to determine which observations, when assimilated, will improve the forecasts. (Abstract ID 10523)

METHANE BUBBLE PLUMES AT HYDRATE RIDGE: MULTIBEAM IMAGING OF TEMPORAL AND SPATIAL VARIABILITY AS PART OF THE OCEAN OBSERVATORIES INITIATIVE

Southern Hydrate Ridge (SHR) will be connected to the Internet in 2013 with a myriad of seafloor sensors connected to the terrestrial grid by high power and bandwidth cables, as part of NSF’s Ocean Observatories Initiative (OOI). SHR is a type-location for methane studies hosting both methane hydrate and methane gas. In 2011, as part of the OOI effort, we used the R/V Thompsons EM 302 multibeam sonar to image the rise height and shape of several bubble plumes at Hydrate Ridge. The rise-height was observed to exceed the top of the local methane hydrate stability field in several of the images, indicating bubble transport and methane entrainment into the shallow water column. These observations were supported by hydrocarbon analyses of samples collected adjacent to the plumes showing methane concentrations in excess of background levels, coincident with the base of the pycnocline. OOI sensors installed in 2013 that include an upward-looking ADCP, mass spectrometer and seismometers will provide real-time data to examine linkages among oceanographic and tectonic events and methane plume formation with data available 24/7/365. (Abstract ID 11879)

EPISODIC CROSS-SHELF TRANSPORT IN THE NORTHERN GULF OF MEXICO

The biogeochemical connectivity between the Northern Gulf of Mexico shelf and waters offshore is subject to complex flow fields and is not well characterized. Here, remotely sensed observations are used to provide insight to both the mechanisms and the resultant ecological impact of a short-temporal large-scale cross-shelf transport event in the Northern Gulf of Mexico (NGOM). The satellite data reveal a filament of high chlorophyll coastal waters, seen as elevated ocean color, extending along the advective path of an eddy positioned near the continental shelf of the NGOM. A comparison of CDOM and fluorescence fields obtained from the MOCNESS sensor aboard NASA’s Aqua satellite quantified the mechanisms leading to the high chlorophyll signal associated with the transport may have varied significantly from previously studied cross-shelf transports in the region. Surface CHL observations showed that the ecological importance of the transport varied significantly with distance from the shelf. Finally, the impact of the event on primary productivity was explored as a means to describe the role of episodic events on the regional carbon budget. (Abstract ID 12706)

DECAD-SCALE OCEAN MODEL SIMULATIONS IN THE GULF OF MEXICO REVEAL INCREASING TRENDS IN OCEAN HEAT CONTENT AND SEASONAL TEMPERATURE EXTREMES

The Navy Coastal Ocean Model (NCOM) is configured at 4km horizontal resolution with a 40-layer z/v vertical structure to conduct 30+ year reanalysis simulations in the Gulf of Mexico (GOM). This NCOM-GOM model is forced by NASA’s Modern Era Retrospective-analysis for Research and Applications (MERRA) atmospheric fluxes, available from 1979 to near-present, and by boundary conditions prescribed from Global NCOM. The objective of these quasi-ideal experiments is to examine and quantify oceanic temperature variability in the Gulf, from statistically significant calculations of sea surface temperature, upper ocean heat content, air-sea heat energy exchange, and other important quantities pertinent to climate change and adaptation. Comparative analyses, versus IPCC A1B results and several observational data collections across the Gulf – including recent Flower Garden Banks Marine Sanctuary field observations (summer 2011), demonstrate robust model skill and reveal enhanced seasonal cycles of ocean temperature along with increasing trends in oceanic heat content. (Abstract ID 11897)

HIGH RESOLUTION ESTIMATE OF SURFACE POTENTIAL VORTICITY FLUXES IN THE REGION OF THE SEPARATED GULF STREAM

Air sea interaction is a key phenomenon that acts to modify the properties of a water mass (and especially its potential vorticity, PV). More precisely, two mechanisms are acting to modify the PV of a water mass: on the one hand, mechanical forcing due to the wind is acting in a region of strong density gradients. On the other hand, heat and freshwater fluxes contribute to modify the PV. In the Atlantic, these fluxes are maximum in the Gulf Stream area. In order to better estimate the rate of formation of mode water, we use a high resolution regional model that we run with successive downscaling. This oceanic model is forced by a slab atmosphere in order to estimate correctly the air-sea fluxes. Since this model resolves meso- and submeso-scale, we are able to map the relative magnitude of the two effects in the presence of eddies. We verify these results using the observations performed in the CLIMODE framework. (Abstract ID 10758)

EFFECTS OF OCEAN ACIDIFICATION ON LARVAL DEVELOPMENT IN ALASKAN CRABS

The goal of this study is to measure the effects of ocean acidification on larval development in Tanner crabs, Chionoecetes bairdi, and Dungeness crabs, Metacarcinus magister, in Alaska. A climate-driven challenge to marine populations is the expected decrease of up to 0.4 pH units in high-latitude waters of North America in the next century. Such a decrease could prove to be detrimental to crabs by causing increased mortality and abnormal development in early life stages. In coastal Alaska, several Tanner and Dungeness crab populations that once supported commercial or sport fisheries have experienced severe stock declines, and recovery might be impeded by additional challenges such as ocean acidification. Here, it is hypothesized that increasing acidity will cause decreased survival, morphometric deformities and decreased calcification rates in larval Tanner and Dungeness crabs. Larvae from females captured in Kachemak Bay, Alaska were raised in flow-through seawater tanks of three different pH levels representing a range expected for the next two centuries in the North Pacific. Larvae were monitored for survival, morphometrics and calcification rate of the exoskeleton during the first zoal stage. (Abstract ID 9393)

NUTRIENT RATIOS AS A TRACER AND DRIVER OF OCEAN BIOGEOCHEMISTRY

Microbial life in the ocean contains immense taxonomic and physiological diversity; yet its collective activity yields global cycles of the major biolimiting elements N and P that are tightly linked. Moreover, the availability of N and P in seawater is closely matched to the metabolic demands of “average” plankton, as plankton composition and the oceanic nutrient reservoirs were mutually influenced. These simple observations have broad implications for the function of nutrient cycles within the Earth system, which can operate either as a biological homeostat that buffers ocean fertility against large changes or as an amplifier of climate perturbations, by alleviating or exacerbating the nutrient limitation of biological productivity and ocean C storage. A mechanistic understanding of these observations and their underlying dynamics must draw upon diverse fields, from physiogy and evolution to physical oceanography and paleoceanography, and must account for processes spanning a wide range of spatial and temporal scales. I will summarize the state of this understanding from the perspective of the nutrient distributions themselves and their changes over time, highlighting the role of physical and biological averaging processes that allow geochemical constancy to emerge from rich biological diversity. WHAT WE HAVE LEARNED: CONNECTING SCIENTISTS WITH STUDENTS THROUGH THE USE OF COMMUNICATIONS TECHNOLOGY

Scientists at Scripps Institution of Oceanography have worked with a group of middle school teachers to teach students about developing new drugs through marine natural products research and the clinical drug discovery process. The participating San Diego Unified School District 7th grade life science teachers routinely teach a unit on drug discovery, and in collaboration with the Center for Ocean Sciences Education Excellence California (COSEE CA), enrich the instruction by providing students the opportunity to communicate face-to-face with marine scientists through an interactive videoconference. Using SKYPE to connect the lab to the classroom, the scientists discuss their work and answer questions about their lifestyle and their path to being a researcher. In addition, the students experience a lab tour and learn about the various jobs people do at the lab. The teacher/researcher team has refined this program over the last three years based on ongoing formative assessment. In this presentation, we will...
discuss what we have learned about developing this type of program and how we plan to implement it more broadly. (Abstract ID 12850)

THE ROLES OF COASTAL GLIDERS IN THE OCEAN OBSERVATORIES INITIATIVE

The NSF-funded Ocean Observatories Initiative (OOI) will make use of ocean gliders for a variety of roles on its coastal and global scale nodes. Within OOI, gliders will be used to make repeated transects to resolve mesoscale variability on seasonal and climatological time scales, for adaptive sampling and process studies, and even to relay data from subsurface moorings via acoustic modem. For coastal scale nodes, gliders will carry a multidisciplinary suite including CTD, chlorophyll fluorescence, optical backscatter, DO2, PAR, and ADCP water velocity sensors. Coastal gliders will maintain a continuous presence on both the re-locatable Pioneer array (initially over the New England/New Jersey shelf and slope) and the permanent Endurance array of the Oregon and Washington coasts. We plan to begin operational deployment of gliders on the coastal scale OOI arrays in May 2012. The science payload and operational strategies place strenuous requirements on the OOI glider design. The three month mission and heavy science payload stretch the battery capacity of available glider platforms. Biofiltering mitigation is also a necessity for these missions. OOI is now testing the Teledyne Webb Slocomb G2 configured to fulfill these requirements. In this talk, we will describe the roles of coastal gliders in OOI, report on the testing progress and update the plans for operational deployments in the coastal scale arrays of OOI. DENTRIFICATION RATES AND CARBON FLUXES IN OXYGEN DEFICIENT ZONES

Denitrification in the main three pelagic oxygen deficient zones (ODZ) of the world’s oceans is thought to account for approximately 30% (60-90 Tg/y) of the combined nitrogen loss from the ocean. However, current estimates are based either on stoichiometric calculations or instantaneous discrete rate measurements and there remains considerable range and uncertainty in the existing numbers. We used published and unpublished sediment-trap carbon-flux numbers to calculate denitrification rates. Trap-flux derived denitrification rates were highest in the eastern tropical South Pacific, 27 nM/d, and lowest in the eastern tropical North Pacific, 5.2 nM/d. The rate for the Arabian Sea was 7.6 nM/d. When rates were fit to a “Martin-type curve” the attenuation coefficient, alpha, was significantly smaller than that generally considered representative for the global ocean (~0.3/m rather than ~0.8/m). Given a mean combined nitrogen deficit of about 7 uM for each ODZ, sediment-trap derived rates suggest water mass replacement times on order 1 to 8 years for ODZ waters. (Abstract ID 12405)

DYNAMICALLY- AND OBSERVATIONALLY-CONSTRAINED ESTIMATES OF WATER-MASS DISTRIBUTIONS AND AGES IN THE GLOBAL OCEAN

We develop a global data-constrained ocean circulation model to infer the distribution of water masses and their ages in the ocean. The model is constrained by temperature, salinity, radionuclides, and CFC distributions in the ocean, as well as independent estimates of sea-surface height and heat and freshwater fluxes. We find that the ocean is ventilated primarily by water masses forming in the Southern Ocean, which make up more than 50% of the ocean’s volume. We also find that more than 60% of interior ocean waters make first contact with the atmosphere in the Southern Ocean, further emphasizing the central role played by the Southern Ocean in the regulation of the Earth’s climate. The mean age of deep waters is greater than 1000 years throughout most of the Indian and Pacific Oceans, reaching a maximum of 1400-1500 years in the mid-depth North Pacific. The mean time for deep waters to be re-exposed at the surface through most of the Indian and Pacific Oceans, reaching a maximum of 1400-1500 years in the deep North Pacific. These findings have important implications for the oceanic uptake of heat and greenhouse gases. (Abstract ID 10921)

ACTIVE AND PASSIVE ACOUSTIC SYSTEMS ON A CABLED OCEAN OBSERVATORY

Cabled observatories are particularly good platforms for supporting both active and passive acoustic observing systems. The continuous power and virtually unlimited bandwidth lends itself naturally to the demands of acoustic technology. The VENUS coastal network, active since 2006 in the coastal waters of British Columbia, has been using a variety of both active and passive systems to probe and monitor the environment. In particular, several well-established active technologies generating rich data records have been deployed, including Acoustic Doppler Current Proﬁlers (ADCP), Acoustic Doppler Velocimeters (ADV), and high-frequency inverted echo-sounders (Zooplankton Acoustic Proﬁlers, ZAP). Passive sounds have been monitored with multi-element hydrophone arrays. Multiple active and passive acoustic systems can interfere with each other, so a variety of synchronizing, sampling, and spatial separation strategies have been employed. With meagin communications, these systems have default conﬁgurations that collect hundreds of megabytes to gigabytes of data per day. The presentation will discuss some of the challenges, solutions, and results associated with acoustic systems on a cabled observatory. Upcoming deployments include the addition of DIDSON acoustic imaging technology. (Abstract ID 10564)

REMOTELY FORCED SUB-THERMOCLINE VARIABILITY AT LOW FREQUENCY IN THE SOUTH-EASTERN PACIFIC

The eastern boundary current systems are connected to the equatorial variability at a variety of time scales through the equatorial Kelvin wave that can propagate along the coast or can reflect as Rossby wave (ER). At low frequency, linear theory predicts that Kelvin wave reﬂects as Rossby waves at almost all latitudes. Here we present an analysis of the subthermocline interannual variability in the eastern South Paciﬁc as simulated by models of various complexity; from linear to eddy-resolving models. The focus is on the energy flux associated with extra-tropical ER and their connection with equatorial Kelvin waves. The WKB theory is used to interpret the simulated subsurface variability. The analysis reveals vertical propagation of energy associated to seasonal and interannual timescales suggesting that a significant share of the mechanical energy of the wind stress along the equator is transmitted to the deep ocean at higher latitudes. A particular focus is put in the vertical energy flux associated to the EL Niño variability, differentiating the two types of EL Niño, namely the conventional EL Niño and the Central Paciﬁc EL Niño. CALCIIFICATION RATES UNDER DIFFERENT CO2 LEVELS FOR THREE BERMUDIAN CORALS MEASURED IN SITU AND IN AQUARIUM

Rising levels of atmospheric CO2 in ocean surface water are causing increasingly unfavorable conditions for calcification of coral reef communities and potentially trending towards net dissolution of calcium carbonate reef substrate. This study tracked the growth rates of three common Bermudian corals, Diploria strigosa, D. labyrinthiformis and Porites astreoides under present and IPCC projected CO2 levels, both in flow-through aquaria, and in situ measurements on the Bermuda coral reef platform. Aquaria specimen were incubated for 10 days at IPCC projected pCO2 levels for 2100, and measured for growth using the buoyant weight method normalized for surface area and initial mass. In situ measurements were conducted at two extreme ends of a naturally occurring carbonate ion concentration gradient on the reef platform, with growth tracked quarterly via buoyant weight. Six months of in situ growth data indicate a faster rate of coral growth in study sites with higher carbonate ion concentration. In contrast, the aquaria study found no significant change in the growth rate of D. strigosa subjected to CO2 levels modeling surface seawater for the year 2100. (Abstract ID 10124)

VERTICAL VELOCITY OF THE DEEP SEA HYDROTHERMAL PLUME OF DANTE AND ITS INTERACTION WITH TIDAL FLOWS

The acoustic scintillation method has been used to study the vigorous hydrothermal plume of Dante within the Main Endeavour vent field (MENV) at the Endeavour segment of the Juan de Fuca Ridge. Forty-day time series of vertical velocity and temperature fluctuations were obtained across the rising plume at 20 m above the Dante edifice in an environment where the flow is dominated by strong (5 cm/s) semi-diurnal tidal currents and a northerly mean residual current (3 cm/s). These measurements provide a window on deep-sea hydrothermal plume dynamics in strong oscillatory cross flows. Plume models that take into account ambient stratification and time-dependent background flows, in conjunction with these measurements, yield insights into entrainment, plume bending, rise height, and, inferentially, mound heat flux. In particular, an integral plume model with an entrainment velocity that is a function of both the plume axial
velocity and the ambient tidal flow perpendicular to the plume axis indicates that increased entrainment occurs during strong cross flows causing the plume to cool, rise more slowly and bend. Results from a separate three-dimensional numerical model show the plume bending with the tidal cycle and having rise heights that vary from ~75 to approximately 250 m for an estimated mound heat flux of 40 MW and a discharge salinity anomaly of ~5 psu. THE EMERGENCE OF STRIATIONS IN THE NORTH PACIFIC CIRCULATION

Recent observation suggest that the mean ocean circulation is characterized by zonal striations in the velocity field resembling the alternation of jet-like features. In this study the generating dynamics of these striations are explored numerically with a set of high-resolution (~10km) long-term (100 year) simulations of the North Pacific. The simulation set are conducted with decreasing level of complexity towards more idealized configuration that allow retaining the essential dynamics and forcing necessary for the striations to develop in the long-term mean. For each model simulation we diagnose the spin-up dynamics of the ocean model and how the onset of the striations, and their location, is sensitive to topography, coastal geometry and different strength of the forcing – which modulates the gyre scale circulation and the degree of non-linearity of the flow field. Results indicate that striations develop from the eastern boundary and migrate in the ocean interior following linear and non-linear beta dynamics. However their appearance in the long-term mean is determined by topographic features along the eastern boundary and the ocean interior that localize in space the vorticity anomalies generating the beta-plumes. (Abstract ID 10837)

THE EFFECTS OF VIOLACEIN-PRODUCING BACTERIA ON MICROZooplankton GRAZING AND PHYtoplankTON GROWTH

Microzooplankton are grazers that are less than 200 μm. They are important in regulating population levels of bacteria and other microorganisms in the ocean. Also they have an important role in the microbial loop transforming dissolved organic carbon and they are an important food source. There are some genera of aquatic bacteria that produce violacein pigment as a chemical defense. It is a highly toxic pigment that has been shown to kill freshwater microzooplankton. We experimentally investigated how violacein-producing bacteria (VPB) affect microzooplankton grazing and phytoplankton growth in estuarine plankton communities. Our results suggest that the addition of VPB to estuarine microplankton communities affects algal growth instead of inhibiting microzooplankton grazing. For VPB to have an effect in the natural environment, in estuaries it has to be at concentration range of ~10^3 ml^-1. In estuaries and coastal seas, estimates of total bacterial abundance range from ~1 x 10^6 ml^-1 to ~2 x 10^7 ml^-1. So, for there to be an effect at least ~10% of bacteria would have to be VPB. VPB could have a negative impact on phytoplankton communities but there could also be a positive impact, the control of blooms the Chesapeake Bay and its tributaries. (Abstract ID 9669)

AN EXAMINATION OF OCEANIC PROCESSES CONTRIBUTING TO THE SST ANOMALIES IN THE NORTH ATLANTIC OCEAN

A one-dimensional mixed layer model is combined with satellite fields to determine the processes responsible for SST anomalies in the North Atlantic Ocean. The model is forced at the surface with heat, momentum and freshwater fluxes. We modify the 1-d model to include geostrophic and Ekman advection of temperature and salinity advection down to 150m. Climatological and time-varying forcing terms are applied in different combinations to estimate their effects. We focus on the many contributions to SST at six locations in the North Atlantic Ocean including the Gulf Stream and its recirculation gyre, the Northwest Corner; the North Atlantic Current, the Labrador Current and the Azores Current. We see a fragile balance between the advection of temperature and of salinity, particularly in the subpolar gyre, where the water column is easily destabilized. Climatological depth dependent corrections to the advection of both temperature and salinity are needed to stabilize the column and can be surprisingly large compared to the advection terms themselves. Adding salinity advection resulted in more reasonable mixed layer depths and SST than temperature advection alone. (Abstract ID 10674)

ABYSSAL WARMING IN THE NORTIC SEAS

Since Greenland Sea Deep Water (GSDW) is the coldest of the three local Deep Waters, Meincke & Rudels (1995) concluded that the sustained warming in the deep Greenland Sea from the early 1970s to the present was due to a progressive shift from vertical exchange (with the cool surface layers) to horizontal exchange (with the relatively warm Arctic Ocean Deep Water (AODW) through Fram Strait), and the accompanying changes in salinity and oxygen were consistent with that view. Dickson & Osterhus (2007) later explained the parallel warming of Norwegian Sea Deep Water at 2000m beneath OWS M as being due to the spread of this warming GSWD through the Jan Mayen Channel (all 2000m). Here we follow the warming signal northwards from OWS M through the Lofoten Basin to Fram Strait, where we conclude that it may explain the steady rise in temperature observed close to the seabed over the last ten years in the deepest part of the watercolumn (2500m) of the HAUSGARTEN-site. Since sea-floor temperature is a known control on the dissociation of gas hydrates from sediments in this area, it is important to develop an understanding of the cause of such a sustained warming trend. If our conclusion is correct, the observed warming there may be the recent expression of a longer trend involving changes in the exchange of deep waters between three ocean basins (Eurasian, Greenland and Norwegian) over a period of 4 decades. And at OWS M and Fram Strait, the deep warming continues. (Abstract ID 9933)

BUILDING AN OCEAN LEARNING NETWORK: FOSTERING COLLABORATIONS WITH THE INFORMAL SCIENCE COMMUNITY

COSEE Florida is a partnership between the Smithsonian Marine Station at Fort Pierce, Indian River State College, Florida Institute of Technology, and Ocean Research & Conservation Association. As a part of the national network of Centers for Ocean Sciences Education Excellence (COSEE), whose mission is "to spark and nurture collaborations among research scientists and educators to advance ocean discovery and make known the vital role of the ocean in our lives", one of the primary initiatives of COSEE Florida is to create an active, statewide Ocean Learning Network through which ocean scientists can broadly disseminate their research in meaningful ways, thereby meeting broader impact requirements. Although in operation for just over 12 months, COSEE Florida has successfully fostered a number of mutually beneficial relationships outside its core group of partner organizations, resulting in opportunities for scientists to engage in educational outreach. This presentation will highlight the collaborations between ocean scientists and informal science facilities, as well as discuss some of the strategies employed to achieve them. (Abstract ID 12124)

GULF OF MEXICO BLOWOUT SCENARIOS USING A COUPLED CIRCULATION-OIL TRANSPORT/DISPERSION MODEL

A Gulf circulation (DeCAST) and oil transport (Shinsho) model is run in ensemble mode, using specified wind and eastern Caribbean Sea inflow over several centuries in a set of scenarios, including different initial conditions, oil and dispersion characteristics. Decades-to-centuries Gulf residence time and pyrolytic thinness, together, imply quasi-laminar cross-pyrolytic mixing, so water mass profiles near and above it are largely controlled by eastern Caribbean Sea conditions. Model deviations from Gulf climatology are used to improve Caribbean inflow. During year 356 a warm eddy forms at the northern tip of a tongue of Loop Current water along the Florida shelf slope, moves westward, merges with a new LC extension, entrains new LC water and intensifies, then separates and migrates westward gracing the Gulf northern shelf-break. Such scenario, although rare, is a potential threat to oil rigs and to rapidly spread entrained oil. (Abstract ID 12144)

**THE CLIVAR AND CARBON HYDROGRAPHIC DATA OFFICE**

The CLIVAR and Carbon Hydrographic Data Office (CCHDO) at the UCDP Scripps Institution of Oceanography is the official data center for the International CLIVAR/CO2 Repeat Hydrography Program. The CCHDO's primary mission is to distribute CTD and hydrographic data sets of the highest possible quality, accompanied by data histories and extensive documentation, to the user community. These data products of WOCE, CLIVAR, IOCCP and other oceanographic research programs. CTD, hydrographic, ocean carbon, and tracer data files are collected from data originators, principal investigators and national data centers. The CCHDO staff check and correct each file for content, format and consistency and assemble them with relevant metadata. Data files are produced in three widely-used formats. Custom formats and projects may be provided by arrangement. New public data files and updates are made available immediately in as-received condition. Additionally, ocean carbon data, quality controlled by CDIAC, are merged into the bottle data files at the CCHDO. The CCHDO also provides its public holdings, to NODC/WDC-A for archive and further distribution. (Abstract ID 12212)

**EXPANDING GOOPS TO INFORM ECOSYSTEM BASED APPROACHES (EBAS) TO MANAGING HUMAN USES OF MARINE ECOSYSTEM GOODS AND SERVICES AND ADAPTING TO CLIMATE CHANGE**

While considerable progress has been made implementing those elements of the Global Ocean Observing System (GOOS) and Global Climate Observing Systems (GCOS) that require geophysical observations and models of the ocean-climate system (emphasizing improved predictions of natural hazards and climate change), implementation of those elements requiring observations and models of biogeochemical and ecological states has been slow. Developing the capacity for sustained provision of these data and information as an integral part of GOOS is the focus of a report of the IOC Panel for Integrated Coastal Observations (PCIC). The report focuses on expanding GOOs to provide data and information needed for rapid detection and timely anticipation of the effects of major drivers of change on key marine ecosystem states and impacts of changes in states. The goal is to expand GOOs to inform EBAs for managing human uses of ecosystem goods and services and adapting to climate change. Essential chemical, biological and biophysical variables are identified and a plan for expanding the Global Ocean Observing System (GOOS) to include essential biogeochemical and ecological observations and models is described. **THE EFFECTS OF UPWELLING-FAVORABLE WIND FORCING ON THE EVOLUTION OF STRATIFICATION AND OXYGEN CONCENTRATION OF THE NORTHERN GULF OF MEXICO IN SUMMER 2011**

Two six-day surveys of the Texas-Louisiana Shelf were conducted in June and August 2011 to estimate the spatial distribution and time evolution of the hypoxic zone of the northern Gulf of Mexico. In June, elevated freshwater volume from Mississippi River flooding was observed across the shelf from Texas to east of the Mississippi River delta. Objectively analyzed fields of dissolved oxygen concentrations show patchy hypoxic (DO less than 2 mg/L) conditions from Galveston Bay, Texas to the Mississippi River delta covered an area of 8450 sq-km. Predominately upwelling-favorable winds influenced oceanic conditions in mid-July leading to widespread normoxic and oligotrophic oceanic waters with little vertical or horizontal variability of multiple parameters on the western continental shelf and highly stratified conditions on the eastern shelf. By August, observations show hypoxia was confined to the stratified eastern shelf and covered 8770 sq-km. A newly developed operational physical circulation numerical model of the southwestern Gulf of Mexico, which includes parameterized oxygen demand, shows good agreement with the observed temperature, salinity, velocity, and oxygen oceanic fields. **DO THICKER HOST TISSUES REDUCE SYMBIOT STRESS IN CINNADARIAN-ALGAL SYMBIOSIS?**

Both host and symbiont influence the stress susceptibility of cnidarian-algal holobions, and many studies suggest a significant role of the host. Thicker host tissues have long been speculated to provide increased symbiont photoprotection, but this hypothesis has not been tested. We compared the photophysiology of the chlorophyte Elliptochloris marina living in symbiosis with two closely related, sympatric sea anemones, Anthopleura elegantissima and A. xanthogrammica. After three months of acclimation in experimental tanks, maximum and effective quantum yield of photosystem II was consistently higher in A. xanthogrammica symbionts. Maximum relative electron transport rates were also higher in A. xanthogrammica symbionts when inside intact tissues, but not directly following extraction of symbionts from host tissues, indicating host-specific differences in the internal light environment. Tissues of A. xanthogrammica were thicker and attenuated more light than those of A. elegantissima, but we found no differences in tissue pigmentation, confirming the role of tissue thickness. The ecological implications of tissue thickness in moderating symbiont stress are highlighted by previously established host-dependent zonation and biogeography patterns of A. marina. **SENSITIVITY OF EQUATORIAL ATLANTIC VARIABILITY TO MEAN STATE BIASES**

Analysis of observed sea surface height, sea surface temperature, and heat flux and reanalysis wind stress and upper ocean temperature show that the Equatorial Atlantic Zonal Mode (ZM) obeys similar physics to the El Nino Southern Oscillation (ENSO): positive Bjerknes and delayed negative feedbacks. This implies the ZM may be predictable on seasonal timescales, but models demonstrate no prediction skill in this region. In this study using different configurations of Kiel Climate Model (KCM), we show that a reasonable simulation of the ZM depends on realistic representation of the mean-state, i.e., surface easterlies along the equator, upward sloping thermocline to the east, with an SST cold tongue in the east. We further attribute the differences among the simulations to the individual components of the positive Bjerknes and delayed negative feedbacks. Our findings indicate that seasonal predictions will have no skill in the Equatorial Atlantic while the coupled models exhibit large mean state errors. (Abstract ID 12961)

**THE UBIRUITY OF DISSOLVED BLACK CARBON IN FRESHWATER ENVIRONMENTS.**

Black carbon (BC) is ubiquitous in the environment, including in the deep ocean. As such, it is of importance in the global carbon cycle, but little is known about the processes controlling its transport and fate in marine environments, particularly in its dissolved form. It has been proposed that dissolved BC enters the ocean environment via fluvial transport to become a significant component of marine dissolved organic carbon (DOC). However, the flux of dissolved BC to the ocean has not been constrained, and no information regarding the BC content in terrestrial DOC on a globally relevant scale has been reported. Here we present a database of dissolved BC based on the BP/CA methodology from about 300 freshwater samples,
range from headwater streams to large rivers, to wetlands, covering a wide range of climatic regions worldwide. Our data show that dissolved BC is ubiquitous in freshwater environments representing about 10% of the terrestrial DOC, and its environmental dynamics seem closely coupled to those of bulk DOC. Consequently, the estimated dissolved BC flux to the ocean is 25 Mt/yr. (Abstract ID 12251)

THE THERMO-CARBON PUMP: MILLENNIUM-SCALE STABILIZATION OF MARINE DISSOLVED ORGANIC MATTER THROUGH THERMOGENESIS

The global pool of thermogenic dissolved organic matter (thDOM or “black carbon”) in the ocean exceeds one petamole (10^15 mole) carbon. The objective of this study was to provide estimates on the global turnover of thDOM. An extensive data set was obtained for the Southern Ocean where several water masses of different origins and ventilation ages join. For global validation, the major deep water masses of the Atlantic and Pacific Oceans were included in this study. We found that the global annual removal of deep-ocean thDOM is approx. 30 gigamoles (10^9 mole C) per year. Assuming a steady-state, this removal rate results in an average age of thDOM in the deep ocean of approx. 35,000 years, being the most refractory component of DOM identified on the molecular level to date. In the deep ocean, thDOM is a conservative property of seawater, and removal of thDOM was only observed at the sea surface. Thermogenesis is the first identified mechanism responsible for millennium-scale stabilization of marine DOM. This process therefore plays a major role in the global carbon cycle. (Abstract ID 9485)

MESOSCALER QUASI-ZONAL ALIGNMENTS IN SST SPATIAL CORRELATION ELLIPSES, ITS LINK TO OCEAN STRATIFICATION AND NON-LINEAR AIR-SEA COUPLING

Evidence is continuing to emerge that the mesoscale variability of the ocean does not average out to zero over extended periods, revealing persistent structural patterns that play a yet understudied role in ocean circulation and air-sea interactions. Our analysis exploits derived objective analysis products for the southeast Indian Ocean from AVHRR sea surface temperature and QuikSCAT scatterometry as well as a state of the art BLUEReanalysis (BRAN). This study reveals quasi-zonal alignments of 2-3 meridional width, in the orientation of spatial correlation ellipses of surface ocean state properties from BRAN. Further analyses shows that the above mentioned surface mesoscale spatial properties are influenced by the mean zonal-jet-like features - otherwise known as ‘ocean striations’ - of the southeast Indian Ocean. A two-dimensional spatial filtering method using Hanning window of 4° half-width reveals underlying signatures of quasi-zonal bandings in the mean SSTs from BRAN and AVHRR. Structural imprints of mesoscale SST are also evident in spatial anomalies of wind-stress satellite observations. Unlike previous studies of mesoscale air-sea coupling, the relationship in this region appears to be non-linear. (Abstract ID 10848)

MODIFIED HALOCLINE WATER OVER THE LAPTEV SEA CONTINENTAL MARGIN

A series of transects carried out in 2002-2009 across the Laptev Sea continental margin show consistent cross-slope differences of the lower halocline water (LHW). Over the slope the LHW core is on average warmer and saltier by 0.39°C and 0.26 psu, respectively, relative to the off-slope LHW. Historical hydrographic data (1990s-2010) also show a distinct cross-slope difference of the LHW over the Laptev Sea continental margins. Over the slope, the LHW is on average warmer and saltier by 0.2°C and 0.5 psu, respectively, relative to the off-slope LHW. Our results suggest that an important part of the heat and salt lost from the underlying Atlantic water (AW) is gained by the overlying LHW over the continental slope area. This implies the role of enhanced vertical mixing over the sloping topography, which contributes to the difference between the on- and off-slope LHW properties. The LHW temperature time series constructed from the on-slope historical records are related to the AW boundary current transporting warm water from the North Atlantic. In contrast, the on-slope LHW salinity is linked to the sea ice and wind forcing over the potential upstream source region in the Barents and northern Kara seas, as also indicated by hydrodynamic model results. A NUTRIENT PARADOX: CLIMATE INDUCED DECLINE IN SILICATE BUT NO APPARENT IMPLICATIONS FOR PHYTOPLANKTON PRODUCTIVITY

Macro-nutrient availability in continental shelf waters of the western Tasman Sea has changed over the last 30 y (increasing nitratesilicate), likely due to decreasing riverine inputs and the increasing southwards intrusion of the Eastern Australian Current (EAC), the western boundary current of the South Pacific gyre. With diatoms assumed to drive primary productivity, nutrient enrichment experiments were performed to test whether resident phytoplankton were silicate-limited. Experiments were conducted in austral spring using 3-day
Dohan, K., Earth and Space Research, Seattle, USA, kdohan@esr.org

problematic for sustaining phytoplankton productivity in the region, but suggests complexity in fulvic acid. The relatively low abundance of diatoms indicates silicate limitation may not be limiting nutrient—nitrogen appears to be the dominant macronutrient driving carbon fixation, dissolved iron concentration, primary productivity, and humic-like substances were measured. Biomass and productivity responses in different water masses showed that silicate is not the limiting nutrient—nitrogen appears to be the dominant macronutrient driving carbon fixation, with potential co-limitation by iron and stimulation of productivity by terrestrial organic matter (fulvic acid). The relatively low abundance of diatoms indicates silicate limitation may not be problematic for sustaining phytoplankton productivity in the region, but suggests complexity in predicting the response of lower trophic levels to future change. THE ROLE OF ACC EDDIES AND WINDS IN ACROSS-SHELF WARM DEEP WATER TRANSPORT IN THE AMUNDSEN SEA

The Amundsen Sea region is undergoing Antarctic ice sheet loss through erosion by warm deep waters flowing southward in across-shelf canyons to and beneath the West Antarctic Ice Sheet. In this area the east-flowing ACC, controlled by the bathymetry, veers southeastward near 210 E and exhibits a double-jet structure between 210 and 235 E and -57 to -52 N. These jets break into energetic, strongly barotropic eddies, many of which travel towards the Amundsen shelf break. The eddy pathways are influenced by bottom topography, winds, and the mean flow in which they’re embedded. The Ocean Surface Current Analyses Real-time product (OSCAR) is a global dataset of surface currents analytically calculated from satellite sensed SSH, winds, and SST. We assess the forcing of onshore warm deep water fluxes by the ACC by comparing OSCAR currents with observed barolonic and barotropic current structures derived using ADCE temperature, and salinity data from a year-long moored time series near the mouth of the westernmost canyon on the Amundsen shelf. (Abstract ID 10803)

TROPICAL ATLANTIC CLIMATE FOR A COARSE AND A HIGH RESOLUTION COUPLED CLIMATE MODEL

Using two fully coupled ocean-atmosphere models (GFDDL-CM2.1: our IPCC-A1B model and basis of GFDDL’s experimental seasonal to decadal forecast system, and CM2.5: a new high-resolution global climate model based on CM2.1), the tropical Atlantic basins in the mean state, the seasonal cycle, and the interannual variations were investigated. Many aspects of the simulation are significantly improved in CM2.5 relative to CM2.1—yet others persist. CM2.5 successively reproduces the annual mean and the seasonal cycle of the rainfall over the Sahel and the northern South America, a subsurface dome of the thermocline in the northeastern tropical Atlantic (known as the Guinea Dome), and the seasonal phase-locking of the interannual variations of the northern tropical Atlantic. This marked improvement is mainly due to a significant reduction in some of the biases in the seasonal meridional circulation of the Intertropical Convergence Zone (ITCZ). Also, the idealized climate change response of the northern tropical Atlantic has been explored, using outputs from present-day Control and carbon dioxide doubling (2 times CO2) experiments with GFDDL-CM2.5. We find that the interannual variations show a significant response to CO2 doubling: the seasonal peak of the interannual variations of the SST over the northern tropical Atlantic moves from boreal spring to early boreal summer, at which time it is about 25% stronger than in the Control run. DETERMINING FACTORS THAT INFLUENCE MOLECULAR QUANTIFICATION OF THE HARMFUL RAPHIDOPHYTE HETEROSIGMA AKASHIWO USING A SANDWICH HYBRIDIZATION ASSAY (SHA)

Molecular techniques for detecting and quantifying harmful algal bloom (HAB) species have become central to research and monitoring to expedite sample processing. One example, sandwich hybridization assay (SHA), directly detects organisms using large subunit rRNA-targeted oligonucleotides. Assay results can be used to approximate cell density. However, it occurs globally, produces ichthyotoxic blooms and SHA has previously been validated for it. This study is part of a broader NOAA-MERHAB award wherein SHA results are directly compared to another commonly used molecular approach, quantitative PCR (qPCR). This program entails a rigorous methods comparison of SHA and qPCR using criteria such as cost, accuracy, sample throughput, range/limit of detection, speed and others for HAB research and monitoring. RECENT ADVANCES AND CHALLENGES IN USING ADAPTIVE SAMPLING TO QUANTIFY PROCESS AND TEST OCEANOGRAPHIC HYPOTHESIS

There has been a growing recognition over the last 20 years that the biological, biogeochemical, and optical dynamics of marine systems are frequently dominated by episodic events or by processes that are spatially concentrated in regions of strong gradients such as those observed in chemoclines, thin layers and fronts. Although much of the progress in this area has been dominated by the use of adaptive sampling to guide the collection of discrete samples from ships for laboratory analysis, recent advances in sensors, deployment systems and near-real time data analysis has opened the door for the autonomous collection and analysis of these samples in situ. Herein, we will first use autonomous profiler data collected during a storm experiment to illustrate the need for new in situ adaptive sampling approaches for quantifying critical processes and testing hypothesis. We will then consider how these challenges might be overcome by incorporating some of the advanced sensors illustrated in other talks in this session into ocean observing systems and then using them to adaptively sample structures and processes at the critical time and space scales needed to test hypotheses. SOURCES AND TRANSPORT OF ZINC AND CADMIUM AND THEIR COMPLEXING LIGANDS IN THE ATLANTIC AND PACIFIC OCEANS: DIFFERENTIAL LIGAND DECAV IN SPECIFIC WATER MASSES

The complexation and chemical speciation of Zn and Cd have been determined in the water column of the Western North Pacific and the Equatorial South Atlantic using anodic stripping voltammetry. A novel mathematical interpretation tool (“Titration Data Interpreter”) enabled precise, non-biased ligand parameter optimization, after which the speciation of Zn and Cd was calculated. The results obtained in these oceanic regions indicate marginal seas and other point sources provide both metals and strong ligands from a combination of riverine, terrestrial, marine and anthropogenic source material. Further, ligands decay with time as they are transported along water masses in both Atlantic and Pacific Oceans, suggesting a relationship to ligands produced in water formation regions and estuaries. A consortium of decaying and non-decaying ligands complexes these two metals, affecting their chemical speciation in surface, intermediate and deep waters, resulting in potentially limiting concentrations of bioavailable Zn and Cd in some water masses, both at depth and where some of them upwelled. HEAT AND FRESHWATER TRANSPORTS BY EDDY MOVEMENTS

Oceanic mesoscale eddies contribute important horizontal heat and salt transports on the global scale. Transport is area-integrated flux across a vertical section, and eddy flux is the time-averaged product of temperature or salinity (T/S) and velocity anomalies with respect to their time means. These statistical covariances can arise from a variety of dynamical processes, and this presentation proposes that the eddy heat and salt transports are mainly due to individual eddy movements. T/S anomalies inside individual eddies (with respect to the ambient water) occur due to geostrophic uplift and depression of the background pycnocline vertical profiles associated with cyclonic and anticyclonic eddies, respectively. Satellite altimeter-measured sea surface height anomaly (SSH) data is used to identify and track individual eddies, and vertical profiles from co-located Argo floats are used to calculate T/S anomalies. The estimated meridional heat transport by eddy movement movement is similar in magnitude and spatial structure to previous eddy covariance estimates from models and the eddy heat and salt transports both are a sizable fraction of the total transports. The importance of eddy transports, in particular by eddy movement, supports the need for an eddy-resolving oceanic model in climate simulation. (Abstract ID 10910)

HOW WELL DO CLIMATE MODELS REPRODUCE NORTH ATLANTIC SUBTROPICAL MIDDLE WATER?

Formation and the subsequent evolution of the Subtropical Middle Water (STMW) involve various dynamic and thermodynamic processes. Proper representation of mode water processes in climate models is important in order to predict future climate change. The North Atlantic STMW, referred to as Eighteen Degree Water (EDW), in three coupled models (GFDL CDA, CM2.1, and NCAR CCSM3.0) are analyzed to evaluate how well EDW processes are simulated, and to examine whether data assimilation improves or degrades model's response to forcing. In comparison with estimates from observations, the data assimilating model (CDA) gives a better representation of the formation rate, the spatial distribution of EDW, and its thickness, with the largest EDW variability along the Gulf Stream path. However, CDA does not capture the observed relationship between EDW volume and the EDW seasonal destruction. Observations show a robust anti-correlation between the upper ocean heat content and air-sea heat flux, with upper ocean heat content leading air-sea heat flux by a few months. This anti-correlation is well captured by CM2.1 and CCSM3.0, but not by CDA. Only CM2.1 captures the observed anti-correlation between the upper ocean heat and EDW volume. This suggests that data assimilation degrades the model's thermodynamic response to forcing. Unlike the observed dominant southward movement of the EDW, the EDW in CM2.1 and CCSM3.0 moves eastward after formation in the excessively wide jet stream in the models. (Abstract ID 10225)

UPPER-LOWER LAYER COUPLING IN LOOP CURRENT EDDIES EKMAN AND FRANKLIN

Arrays of moored current meters and bottom mounted pressure equipped inverted echo sounders (PIES) centered near 28°N, 87°W were deployed in April 2009. Data were recovered via mooring rotation or telemetry in July and November 2010. Two Loop Current Eddies form during the 15-month observational period: Eddy Ekman in summer 2009 and Eddy Franklin in summer 2010. Lower-layer flows are not visually coherent with upper-layer Loop Current flows, and the principal axes of the standard deviation ellipses and the mean vectors are not, in general, aligned with those of the surface layer. In both detachment events, a marked increase in lower-layer eddy kinetic energy occurs coincident with the development of a large-scale meander along the northern and eastern parts of the Loop Current front. Lower-layer eddies develop in a pattern reminiscent of developing baroclinic instabilities. These growing and southward propagating meanders along the west Florida slope appear to be the major mechanism that causes these eddies to initially detach. (Abstract ID 9699)

APPLICATION OF PROTEOMICS TO ASSESS THE SYNERGISTIC EFFECTS OF ELEVATED TEMPERATURE AND OCEAN ACIDIFICATION ON TEMPERATE MARINE CALCIFYING ORGANISMS

All living organisms respond to environmental changes through changes in the expression of multiple genes and proteins. Ongoing environmental changes, in particular decreasing ocean pH (ocean acidification or OA, as a result of increasing seawater pCO2) and increasing surface seawater temperature, represent additional environmental stimuli which may induce expression changes in marine organisms. The red coralline algae Lithothamnion glaciaceum, is a marine biogenic calcite which is likely to be structurally very sensitive to the changing climate. Therefore, any OA or temperature induced changes at the molecular level may have an unprecedented impact on marine ecosystems. Here we examined the algae proteome under control conditions (seawater pH 8.0) at either 16°C or 12°C and analysed quantitative expression changes of distinct proteins known to be involved in biomineralisation, in response to acidified conditions (pH 7.7) at the two temperatures. This study presents evidence of how OA and elevated temperature may affect this calcifying marine organism based on molecular level analysis and highlights the benefits of using this systems based approach to investigate the effects of global climate change in marine systems. CONSISTENT TRENDS AND PATTERNS OF INTERANNUAL VARIABILITY IN SURFACE OCEAN CO2 AT CONTRASTING SITES WINDWARD AND LEeward OF THE HAWAIIAN ISLANDS

Sustained time-series have provided compelling evidence for progressive acidification of the surface oceans through exchange with the growing atmospheric reservoir of carbon dioxide. However, there are few such long-term programs, and extrapolation of results from one site to larger oceanic expanses is hampered by the lack of spatial coverage inherent to Eulerian sampling. Since 1988, the HOT program has conducted near monthly sampling of CO2 system parameters at Station ALOHA, a deep ocean site windward and 100 km north of Oahu, Hawaii. Since 1990, parallel surface measurements have been made at Station Kabe, a leeward site 10 km from the island and on the opposite side of the Hawaiian Ridge. The observed timescales of CO2 system variability are explained by a combination of annual seasonality, a linear trend and an 11-year cycle driven by salinity fluctuations. Despite having different physical settings, the sites exhibit identical linear rates of surface pCO2 increase and pH decrease, suggesting that atmospheric forcing dominates over local dynamics in determining interannual CO2 variability in the surface waters of the North Pacific Subtropical Gyre. STRAIN-SPECIFIC RESPONSES TO NITROGEN SOURCE IN THE COCCOLITHOPHORE EMILIANIA HUXLEYI

Global warming and ocean acidification are predicted to increase nitrogen fixation and decrease nitrification, resulting in higher ammonium/nitrate ratios in ocean surface waters. Shifts in nutrient sources coupled with increasing seawater temperatures and changing ocean carbonate chemistry will likely affect calcifying marine phytoplankton (i.e., coccolithophores) which play an important role in the global carbon cycle. The world’s most abundant coccolithophore, Emiliania huxleyi, exhibits high inter-strain variation in genotypy, morphology, and physiological response to environmental influences. E. huxleyi’s response to environmental change is likely genetically based and oceanic processes involving coccolithophores may depend on specific genotypes in blooms. We investigated strain-specific variation in nitrogen metabolism using four strains of E. huxleyi, two type A (CCMP371, RCC 1258) and two type B/RCC (RCC 1211, NS10Y), grown on three different nitrogen sources: nitrate, ammonium, and urea. Growth rates in RCC 1258 and CCMP371 were highest in ammonium, while RCC 1211 and NS10Y grew slowest in ammonium. Inters-strain variation in response to nitrogen source could influence distribution, abundance, and ultimately carbon transport to the deep ocean and the global carbon cycle. (Abstract ID 10678)

IMPACTS OF LARGE TIME SCALE ATMOSPHERIC FORCING (PDO AND NPGO) ON EUPHASIA PACIFICA POPULATION BIOLOGY IN THE CALIFORNIA CURRENT FROM 1991-2008

Long time-scale atmospheric patterns, the Pacific Decadal Oscillation (PDO) and the North Pacific Gyre Oscillation (NPGO), impact coastal productivity primarily through variation in surface water origin, and subsequent variation in associated plankton assemblages. The krill species Euphausia pacifica is an important trophic link connecting phytoplankton to higher trophic level predators and are present in the California Current zooplankton community during all phases of the PDO and NPGO. We present results from a coupled ocean circulation and biological model that explores the variability in E. pacifica population biology off Northern California in relation to long-time scale atmospheric forcing. Ocean simulations were run from 1991-2008 using the Regional Ocean Modeling System (ROMS), coupled with a Nutrient-Phytoplankton-Zooplankton-Detritus (NPZD) model and a 3-D individual-based model (POPCYCLE) parameterized to represent E. pacifica. Results of the model indicate that the PDO and NPGO had a significant impact on krill condition, abundance, and egg production, but had little impact on spatial distribution in the Northern California region. Our model results emphasize the within species change in population biology that can arise from large time-scale atmospheric forcing. (Abstract ID 12511)

INTERNAL WAVE GENERATION, PROPAGATION, AND DISSIPATION IN THE BEAUFORT GYRE

As a result of the decreasing trend in seasonal sea-ice cover in the Arctic Ocean, internal gravity wave generation by storms is increasing. Our goal is to quantify this correlation and characterize the propagation and breaking of these waves in the Beaufort Gyre. In the strongly stratified upper water column, at depths of roughly 200-300m (the top of the Arctic Water layer), downward propagating internal waves encounter a double-diffusive staircase composed of multiple layers of near-constant density. The vertical scale of each layer is smaller than that of the waves, and the layers are persistent in time with large horizontal extent. We investigate interactions between this unusual stratification and the internal wave field using a combination of theory and observations (including salinity and temperature data collected during the last decade from ice tethered profilers and moorings). In particular, we examine changes in the stratification of the double-diffusive staircase due to mixing caused by breaking internal waves and investigate how these changes affect vertical heat fluxes and circulation in the Beaufort Gyre. DECADAL ESTIMATES OF PRODUCTIVITY BY PTEROPODS AND LARVAECEANS IN THE COASTAL GULF OF ALASKA

The thecosome pteropod, Limacina helicina, and larvaeceans have been shown to be dominant components of the juvenile pink salmon diet. These gelatinous plankton are understudied due to their fragile structure that is easily damaged during collections. Preliminary estimates of their composition, abundance and biomass generated along the Seward Line in the Gulf of Alaska show high variability, partially due to the initial focus on the more dominant crustacean zooplankton. We present a refinement of these preliminary numbers and are extending the length of observation to over a decade. By applying literature-derived growth rates, we estimate the potential productivity levels of these groups in the Gulf of Alaska. As there is great uncertainty in the applicability of existing growth rates for the pteropod Limacina helicina, future work will target culturing them in the laboratory. Ultimately, we aim to explore if larvecean or pteropod biomass, or production, are correlated to regional patterns of pink salmon survival. (Abstract ID 12259)

A COMPARISON OF NORTH PACIFIC AND NORTH ATLANTIC SUBTROPICAL MODE WATERS IN A CLIMATOLOGICALLY-FORCED MODEL

Subtropical mode water (STMW), a water mass with homogenous temperature and density and low potential vorticity, is formed in the subtropical gyres of both the North Pacific and North Atlantic Oceans. Eighteen Degree Water (EDW) in the Atlantic and North Pacific Subtropical Mode Water (NPSTMW) in the Pacific have many similarities, including the basic formation processes and physical characteristics. This analysis compares properties and intrinsic oceanic variability of EDW and NPSTMW, within the framework of a high resolution model with climatological atmospheric forcing. Interannual variability is evident in the volume and characteristics of EDW and NPSTMW, but the magnitude of variability is small. The most significant differences are found in the average ages. Circulation patterns lead to a higher average age in the North Atlantic, as EDW is more likely to be advected away from the formation region and remain subducted in the North Atlantic, while NPSTMW is more likely to be reintroduced the following winter in the North Pacific. Connections with western boundary current variability are explored. (Abstract ID 9618)

PAYING IT FORWARD: ENGAGING SCIENTISTS IN COMMUNICATING OCEAN SCIENCE TO VOLUNTEER INTERPRETERS

Volunteer interpreters play an integral role in communicating ocean science to the public in informal science education settings, such as state parks, aquariums and science centers, and scientists are a valuable source of knowledge and information for training these interpreters. Evaluation data collected by COSEE Pacific Partnerships for the Oregon Coastal Master Naturalist Program highlights the value of engaging scientists as workshop instructors for interpretation audiences, and the challenges faced in attempting to effectively communicate science to those who communicate science with the public. Data was collected between May 2010 and September 2011 during the pilot phase of the Oregon Coastal Master Naturalist Program, and includes observations, interviews and surveys with both workshop instructors and participants. (Abstract ID 12255)

WHO’S HELPING WHO!? THE MULTIFACETED VALUE OF ENGAGING OCEAN SCIENTISTS IN PROFESSIONAL LEARNING COMMUNITIES

Professional learning communities (PLCs) are one model for helping improve collaboration between scientists, educators and public audiences and hold inherent value for engaging scientists in educational and outreach programming. This session discusses evaluation findings from three different education and outreach programs in California and Oregon, including the Exploratorium’s Embedding NOAA in a Public Learning Laboratory, Oregon Coast Marine and Aquatic Partnership, and the Oregon Coastal Master Naturalist Program. Findings from these programs highlight the variety of ways collaboration in these communities are valuable to all members when members begin to recognize that they are both simultaneously learners and teachers. The findings also suggest that collaboration in PLCs does not happen naturally, but rather requires that particular strategies are necessary to support learning in all directions. We argue that scientists in PLCs have the potential to not only communicate science content but also learn about audiences, audience needs, and tools for communicating effectively. Concurrently, publics (including formal and informal educators) can benefit from PLCs by...
recognizing that they are equal contributors to the conversation around both science content and effective communication. (Abstract ID 12219)

The ROLE OF LARGE-SCALE PHENOMENA IN VARYING THE SUBDUCTION OF MODE WATERS IN THE PACIFIC

Subantarctic Mode Water (SAMW) is a key player in the storage of anthropogenic carbon in the Southern Ocean. SAMW forms in regions where the deep mixed layers and wind-driven circulation are strongly associated with two large-scale phenomena, El Niño-Southern Oscillation (ENSO) and the Southern Annular Mode (SAM), particularly in the Pacific Basin. We use an eddying, data-constrained, global ocean and sea ice model solution to diagnose the influence of ENSO and SAM on the 1992 to 2009 variability in subduction of SAMW. We individually diagnose the geostrophic, eddy, and Ekman pumping components of subduction. We find that ENSO and SAM combined accounts for >50% of the variance (>30% individually) in the inter-annual variability of the subduction of SAMW, however; this strong influence is concentrated primarily in the Central and Eastern Pacific. In these regions, we find that strong positive SAM/La Niña (strong negative SAM/EI Niño) phases coincide with increasing (decreasing) SAMW subduction rates. We conclude that ENSO and SAM have a significant role in driving inter-annual variability in Pacific SAMW ventilation. (Abstract ID 11993)

ON THE ROLE OF ADVECTION ON THE ECOLOGY OF ARCTIC AND SUBARCTIC SEAS

A brief review of water mass advection between the Arctic and Subarctic regions and the effects on their ecology will be presented. The influence of Arctic outflows through Fram Strait, the Barents Sea and the Canadian Archipelago on the subarctic regions and the inflow of Pacific waters through the Bering Strait and of Atlantic Waters through the Fram Strait and the Barents Sea on the Arctic will be discussed. In addition to describing temperature and freshwater fluxes between the two regions, the role of advection of sea ice from the Arctic and its associated flora and fauna to the Subarctic will be mentioned. Nutrient fluxes and influences on stratification will be presented in terms of their effects on phytoplankton production. Advection of water masses also transports zooplankton communities between the two regions, as well as some ichthyoplankton. Brief mention will be made on the role of fronts between outflowing Arctic Water and inflowing Pacific and Atlantic Water. Possible future changes in advective fluxes between the Arctic and Subarctic will be highlighted along with their possible effects on the marine ecosystem. (Abstract ID 12893)

MODE WATERS IN THE PACIFIC:

Suspended sediment dynamics in Corte Madera Creek (Marin County). Using moored suspended-sediment concentrations in the estuary. Given these uncertainties, we investigated can be transported to and deposited in the tidal reaches of these tributaries, further reducing dissolved-sediment concentrations in the estuary. Given these uncertainties, we investigated suspended-sediment dynamics in Corte Madera Creek (Marin County). Using moored acoustic and optical instruments, we observed water velocity and suspended-sediment concentrations continuously for water years 2010-2011. During periods of low stream discharge, suspended-sediment concentration was greatest during flood tides. During periods of high stream discharge (corresponding to rainfall-runoff events), greater suspended-sediment concentrations were observed on ebb tides. These results suggest that estuarine tributaries may alternate seasonally as a sediment sink or source for the San Francisco Bay. (Abstract ID 11995)

SUSPENDED SOLUTERN PCO:

IN-SITU PCO MONITORING IN A CORAL REEF ENVIRONMENT: EFFECTS OF OCEAN ACIDIFICATION ON BIOGEOCHEMICAL AND PHYSICAL PROCESSES

Four buoys, deployed in the coastal waters of Hawaii (three since 2008 and one since 2011), are producing high temporal resolution CO₂ records in four different coral reef environments as part of an integrated effort to understand CO₂ dynamics around Oahu. Each buoy measures CO₂ concentrations in both the atmosphere and seawater and serves as a platform for a variety of sensors measuring physical and biogeochemical parameters in support of the PacOOS water quality efforts. These data records, combined with data from a prior buoy deployment, synoptic spatial sampling, and in-situ experimental studies allow us to characterize how the biological cycles of productivity/respiration and calcification/dissolution and the physical process of ocean-atmosphere gas exchange occur on hourly to interannual time scales. The four locations, which encompass the backreef and forereef of a barrier reef, as well as two fringing reef sites, one of which is subjected to significant urban runoff, display a wide range of variability in CO₂ system dynamics in both the short- and long-term and demonstrate the need for high frequency data to accurately characterize the CO₂-carbonic acid system. (Abstract ID 10760)

A GLOBAL APPROACH TO THE ASSESSMENT AND MANAGEMENT OF LARGE MARINE ECOSYSTEMS

-Dr. Kenneth Sherman – NOAA/NMFS, Director Narragansett Laboratory, Narragansett, RI
- Dr. Alfred M. Duda – Senior Advisor, Global Environmental Facility, Washington, D.C.

Large Marine Ecosystems (LMEs) support 80% of the world's marine fisheries. The goods and services of LMEs, including fisheries, provide an estimated $12.6 trillion annually to the global economy. Presently, LMEs are being degraded by overfishing, coastal pollution, nutrient over enrichment, habitat destruction, biodiversity loss, and climate change. In a global effort to recover, develop, and sustain the world’s LMEs, economically developing coastal countries in Africa, Asia, Latin America, and Eastern Europe are implementing LME projects with grants from the Global Environmental Facility (GEF) and investment funds from the World Bank. The GEF in partnership with NOAA, five UN agencies, two NGOs, and the World Bank is assisting over 100 countries with $3.1 billion in financial aid to introduce ecosystem-based assessment and management practices using a modular approach to assess changing conditions in LME productivity, fish and fisheries, pollution and ecosystem health, socioeconomics, and governance. There has been substantial progress in applying the concept of ecosystem carrying capacity to actions for recovering and sustaining LME goods and services. (Abstract ID 10327)

LIGHT INTERACTS WITH OCEAN ACIDIFICATION TO ALTER CALCIFICATION AND SURVIVAL OF CORAL RECRUITS

The influence of light on coral calcification is relatively well understood, however the effect of light has been absent from investigations of the effects of ocean acidification (OA) on coral calcification. We incubated 2 day-old Pocillopora damicornis recruits in 1 of 5 light treatments (226, 122, 70, 41, 31 µmol photons m⁻² s⁻¹) under ambient (493 µatm) or high pCO₂ (878 µatm) for 5 days. Calcification was significantly affected by pCO₂ and the interaction of pCO₂ and light. Recruits in high pCO₂ displayed a contrasting relationship to light compared to ambient pCO₂, resulting in a large disparity in calcification at intermediate light intensities, but similar rates at high and low light intensities. Survival was significantly affected by both light and pCO₂, and was highest at 122 µmol photons m⁻² s⁻¹ in both pCO₂ treatments; survival was not correlated with calcification. The demonstration that OA has light-dependent effects on the calcification of coral recruits suggests that some of the contrasting results that have been reported for the effects of OA on corals could be a result of dissimilar light regimes. (Abstract ID 10899)

ON-EDDY COMPENSATION OF ENHANCED SEA-TO-AIR CO2 FLUXES DURING POSITIVE PHASES OF THE SAM

It is thought that the recent positive trend in the Southern Annular Mode (SAM) has weakened the Southern Ocean CO₂ uptake because of enhanced wind-driven upwelling of dissolved inorganic carbon (DIC). For greater mechanistic understanding, we made two simulations with a widening circulation model coupled to an ocean carbon model in a regional Southern Ocean configuration (28 km resolution at 60°S). The first simulation is run under preindustrial
atmospheric CO₂ but with modern interannual atmospheric forcing from reanalysis products; the second simulation uses the same forcing but adds a wind anomaly consistent with SAM positive phases. The response of natural CO₂ fluxes to the SAM is driven mainly by the competition between anomalous increases in surface DIC and alkalinity. Mixed-layer DIC increases mainly due to entrainment and diffusion, but there is little contribution from vertical advection. Below the mixed layer, one-fifth of the simulated increase in Ekman-induced DIC transport is compensated by transport from standing and transient eddies. Yet this simulated eddy compensation probably underestimates that of the real ocean because our eddy-permitting model only begins to resolve the eddy spectrum. (Abstract ID 9696)

ANTHROPOGENIC AMMONIUM ECOSYSTEM EFFECTS: FROM RIVER TO ESTUARY TO COASTAL OCEAN.

Ammonium loading to the Sacramento River at a rate of 15 tons N daily, reduces primary production in the river and portions of the San Francisco Estuary (SFE), and also influences the pattern of primary production along the coast to the north of the Golden Gate. At the highest concentrations of ammonium the uptake of ammonium by the phytoplankton is inhibited. At relatively low concentrations of ammonium, nitrate uptake is suppressed. Both effects contribute to the very low primary productivity in SFE. Patterns of dissolved inorganic nitrogen (DIN) and primary productivity in the river, SFE and the adjacent coast will be presented. Criteria based on ammonium loading, river flow, and ammonium concentration have been developed to predict the conditions allowing spring blooms of phytoplankton to occur. A simple model incorporating these criteria predicts an ecosystem with 2 stable states, a low ammonium, high productivity mode and a high ammonium, low productivity mode. (Abstract ID 12823)

DYNAMICS OF INTENSE NEAR-BOTTOM CURRENTS ALONG THE SIGSBEE ESCARPMENT, NORTHERN GULF OF MEXICO.

The Sigbee Escarpment is located at the offshore edge of the Central Slope south of the Louisiana-Texas Shelf where the seafloor drops dramatically to the Sigbee Plain of the Gulf of Mexico Basin. Deep ocean dynamics over the Sigbee Escarpment has been extensively studied over the last 15 years. Strong bottom intensified currents exceeding 1 knot (~0.5 m/s) have been recorded frequently along the escarpment. Despite the fact that strong deep events are well represented in the observational data, dynamics and generation mechanisms of the bottom intensified currents in the region are still not understood. Major questions still remain unanswered. To address some of these questions, a model study of the deep ocean dynamics in the area was conducted. Presented study analyzes results from a high-resolution model of the Sigbee Escarpment nested in the Hybrid Coordinate Ocean Model (HYCOM) of the Gulf of Mexico. Dynamical interpretation of simulated bottom intensified strong currents over the Sigbee Escarpment is suggested. Characteristics of simulated wave motions and propagation pathways of the strong events are discussed. (Abstract ID 10298)

RADIATION LEVELS IN THE CENTRAL PACIFIC OCEAN AFTER THE FUKUSHIMA DIACHI NUCLEAR POWER PLANT ACCIDENT

The March 11, 2011 earthquake and tsunami made substantial damage to the Fukushima Daiichi Nuclear Power Plant. Electrical resistivity profiles show that the mound as a whole is underlain by 1-2 Ohm-m material, whereas the resistivity within the fault zones is higher (3-5 Ohm-m). There are also isolated 100 Ohm-m anomalies within the fault zones that extend to a depth of 40 m or more. I propose that the 100 Ohm-m anomalies are associated with thick lenses of hydrate within the fault zones and that the 3-5 Ohm-m zones contain thinner deposits of hydrate. The various features of the mound could be explained by the vertical movement of the thick hydrate lenses due to buoyancy forces. I use a finite element model to test the mechanical viability of this hydrate extrusion mechanism. The model shows that for reasonable values of sediment density and strength, hydrate lenses should begin moving upward after reach thicknesses of 1-2 m. (Abstract ID 12230)

THE FINE SCALE HYDRODYNAMICS OF A SLOPING CORAL REEF: EILAT, ISRAEL.

Many corals are subjected to turbulent, wavy environments due to their inherent rough structure, and proximity to shorelines. However, large daily temperature variations in these shallow coastal environments produce a stratified environment thus damping turbulence. In this study we seek to understand how stratification affects turbulence above the corals, and how stratification affects the vertical fluxes of salt, heat, and plankton. In situ high-resolution velocity instruments were deployed to sample continuously over a 10 day period to measure key turbulence parameters including dissipation, Reynolds stresses, and turbulent fluxes at various depths above a sloping coral reef. Utilizing the work of Shih et. al. 2005, Bouffard (2011), and Ivey and Imberger (1991), these parameters were used to estimate mixing efficiency and vertical eddy diffusivity over the corals. In addition, phytoplankton concentration measurements were also made using a system of vertical pumping arrays arranged to form a 'control volume'. The coupling of the turbulence parameters phytoplankton measurements allows us to understand how the flux of inorganic nutrients is altered by changing hydrodynamic conditions. (Abstract ID 11471)

EVIDENCE FOR VIRUS INFECTION IN THE CALANOID COPEPODS A. TONSA AND L. AESTIVA IN TAMPA BAY, FLORIDA

Copepods, the most abundant mesozooplankton, play important roles in marine food webs as food sources for higher trophic levels and mediators of carbon deposition to the ocean interior. However, little is known about causes of natural mortality in marine mesozooplankton. Using viral metagenomics, we have discovered novel single-stranded DNA viruses in the calanoid copepods Acartia tonsa and Labidocera aestiva from Tampa Bay, Florida. The copepod viruses have weak amino acid similarity to Circoviridae, but diverge significantly from vertebrate circoviruses. The copepod circoviruses are species-specific and were not detected in other zooplankton or bulk seawater. Quantitative PCR revealed viral loads of up to 10⁵ circoviruses per individual L. aestiva copepod, with active viral transcription detected by quantitative RT-PCR in several individuals. Combined with transmission electron micrographs demonstrating the presence of virus-like particles in A. tonsa tissue, these data suggest that virus infection may be common in natural populations of copepods. OCEAN UPTAKE OF ANTHROPOGENIC HEAT AND CARBON IN TWO EARTH SYSTEM MODELS OF ALTERNATIVE OCEAN PHYSICAL CONFIGURATION

We assess the regional and global controls on ocean heat and carbon uptake in two new global coupled carbon-climate Earth System Models, ESM2M and ESM2G which differ exclusively in the physical ocean component; ESM2M uses Modular Ocean Model version 4-1 with vertical pressure layers while ESM2G uses the Generalized Ocean Layer Dynamics model with interior isopycnic coordinates. While each model has its advantages and disadvantages, both give similar fidelity in model's climate. Because both models utilize the same biogeochemical algorithms, this comparison affords us the unique ability to assess the role of ocean physical configuration.
on ocean heat and carbon uptake. While the baseline characteristics of these models have clear differences with often opposing biases relative to observations, we find remarkable similarity in the heat and carbon uptake magnitudes and patterns. While the Western North Atlantic dominates in terms of regional burden via its overturning circulation, the mid-latitude ventilation regions (mostly the Southern Ocean) dominate the global total. EXCITATION OF MODE-TWO INTERNAL WAVES BY A MODE-ONE INTERNAL WAVE AND A MESOSCALE EDDY

The internal tide and mesoscale eddies are prevalent in the world's oceans however the interaction between them is not well understood. Here we conduct numerical experiments to investigate the interaction between a mode-1 internal wave and a mode-1 eddy. The analytic eddy is prescribed in the interior of a square domain and, after an adjustment period, analytic mode-1 internal waves are forced at the western boundary. The mode-1 waves then propagate eastward, interacting with the eddy, and eventually get absorbed by a sponge layer at the eastern boundary. Analysis of the resulting flow fields shows that a mode-2 internal wave is produced with energy levels of 1-4% of the forced mode-1 wave. A mode-3 internal wave is also produced, but at a much lower energy level. The strength of the mode-2 waves has a directional dependence which depends on the eddy. Internal wave focussing/shadow regions are observed behind the eddy. The enhanced energy levels in the focussing regions have implications for the internal wave energy cascade. (Abstract ID 11289)
analysis of the preformed and remineralised PO4 of seven biogeochemical ocean circulation models (OPA-PISCES, MPIOM-HAMOCO, CCSM3-BEC, MOM4-BLING, UVIC, CSIRO and MOM3) against observations (WOA). Deficiencies in the physics and high-latitude biogeochemistry are obvious from the analysis and compensated in some of the models most likely by tuning the biogeochemical model to fit PO4 fields. Inspection of total nutrients alone is hence not sufficient, since the same nutrient distribution may be achieved through very different combinations of ocean physics and biogeochemistry. Implications on suboxic regions extension are explicited. (Abstract ID 11823)

MODELLING THE INTERCONNECTION BETWEEN ECOSYSTEMS AND BIOGEOCHEMISTRY IN A CHANGING OCEAN

We explore the interconnection of phytoplankton community and function, and the interaction with the biogeochemical and climate system. We use a numerical model of the global ocean that resolves many phytoplankton types with a range of functionality, and many different combinations of nutrient, temperature and light requirements. A suite of integrations, along with simple ecological theory, are used to illustrate how the planktonic ecosystem exerts strong control on the biogeochemical environment and how this control may alter in a future warmer ocean. Temperature-driven increase in biological rates promotes higher production, significant re-arrangement of species habitats, but little functional shifts in the community. In contrast lower nutrient supplies due to a slower circulation and increased stratification leads to reduced production and sharp shifts in functionality. We examine how these two aspects of a changing ocean compete in different regions, leading to alterations in the ecosystem, biogeochemistry, and ultimately the export of carbon to the deep ocean. OBSERVATIONS BENEATH PINE ISLAND GLACIER, WEST ANTARCTICA

Thinning ice in West Antarctica, resulting from acceleration in the flow of outlet glaciers, is currently contributing about 10% of the observed rise in global sea level. Pine Island Glacier (PIG) in particular has shown nearly continuous acceleration and thinning throughout the short observational record. Rapid thinning of the floating ice shelf that forms where the glacier reaches the coast, driven by changes in ocean heat transport beneath it, and the consequent inland retreat of the line separating grounded and floating ice has been postulated to be the cause. Evidence gathered by shipboard observations and an Autonomous Underwater Vehicle (AUV) operating beneath the ice shelf shows that PIG was recently grounded on a transverse ridge in the sea floor, and that warm seawater now flows through a widening gap above the submarine ridge, rapidly melting the thick ice of the newly-formed upstream half of the ice shelf and delivering the upwelled melt water to adjacent bays. The ocean circulation beneath the glacier tongue is vigorous and topographically controlled, reaching 20 cm/s along the ridge crest and near the grounding line. (Abstract ID 9828)

SEDIMENTARY RESPONSE OF THE DELAWARE ESTUARY TO EXTREME STORM EVENTS IN 2011

Passage of Hurricane Irene and Tropical Storm Lee through the Delaware River Basin in summer 2011 provided a rare view of an estuary's response to extreme river discharge and wind forcing. Freshwater flow peaked at 4,100 m^3/s during Irene and 5460 m^3/s ten days later during Lee. Over a million tons of suspended sediment was supplied to the watershed from the upper Delaware Estuary in association with these events, exceeding the typical load generated during an entire year. Riverflow and winds forced by Irene completely damped the flood tide in the upper estuary on 27 August, enhancing seaward transport of freshwater and sediment. During a post-storm hydrographic survey, the salt limit and turbidity maximum were observed during Lee. (Abstract ID 10664)

A BIOCHEMICAL UPPER OCEAN STATE ESTIMATE IN THE SOUTHERN OCEAN GASER REGION

The processes controlling colored dissolved organic matter (CDOM) in the upper ocean are uncertain, specifically, the importance of advection, photodegradation, thermocline entrainment and in-situ biological sources. This issue is addressed using a biochemical/physical state estimate in the Southern Ocean Gas Exchange Experiment (SO GasEx). A high-resolution ocean general circulation model with realistic physics simulates the SO GasEx cruise near South Georgia in March 2008. The state estimate uses in-situ CDOM, temperature, salinity, and deliberately-released sulfur hexafluoride measurements, and remote-sensed CDOM, sea level anomaly, and sea surface temperature measurements. The method of Lagrange multipliers is used to find the initial conditions that generate the time-evolving biochemical and physical fields that fit the observations best. Photo-degradation of CDOM is included explicitly, but biological sources of CDOM are not. The state estimate accurately fits the data, implying that the biological CDOM sources and sinks are indistinguishable from zero. Lateral advection is very important for the mixed-layer CDOM, however. Both photo-degradation and thermocline entrainment are moderately important and decrease mixed-layer CDOM with timescales of 2-4 weeks, averaged over the region. (Abstract ID 10459)

TRANSCRIPTOME AND PROTEOME PROFILING IDENTIFIES PATHWAYS OF NUTRIENT METABOLISM IN AUREOCOCCUS ANOPHAGEFFERENS.

Harmful Algal Blooms (HABs) such as the brown-tides caused by Aureococcus anophagefferens are a global problem. Recent analysis of the A. anophagefferens CCMP 1984 genome suggests it is uniquely adapted to the estuaries where it occurs, as the genome contains a large number of genes for the metabolism of nitrogen (N) and phosphorus (P). Here, transcript (N and P) and protein (P) profiling were conducted to screen for genes associated with N and P metabolism. Transcripts and proteins associated with P deficiency included a phosphate transporter, and an alkaline phosphatase and transcripts associated with N deficiency included an ammonium transporter and a xanthine uric acid(VitaminC) permease. Additional studies have confirmed that these genes are regulated by P and N and their expression can be identified in field populations. We are in the process of additional transcriptome profiling of A. anophagefferens CCMP 1850, and metatranscriptome profiling of samples taken during brown-tides. Together, this type of culture and field study will provide a comprehensive view of metabolic potential in A. anophagefferens , and likely drivers of bloom formation and decline in this and other harmful species. COMPOSITION AND FUNCTIONAL DIVERSITY OF COPEPOD-ASSOCIATED PROKARYOTE COMMUNITIES IN A GREENLANDIC FJORD

We compared the prokaryote communities in pelagic water samples and those associated with two arctic copepod species, Calanus finmarchicus and Metridia longa, along a salinity gradient in Godthåbsfjord, Greenland. Based on DNA fingerprinting, the two copepod species carried distinctly different prokaryote communities, which were also different from that in the ambient water. Analyses of Bacteria, Alpha-proteobacteria, and Archaea revealed spatial variation in community structure along the salinity gradient. We also used PCR screening to compare the functional gene diversity between free-living and copepod-associated prokaryote communities. Functional genes for methanogenesis, nitrogen fixation, denitrification and ammonium oxidation were detected in the copepods, but were rare in the ambient water. Our results suggest that the presence of copepods support a higher-than-expected diversity of prokaryote community in the fjord, and that these host organisms function as microhabitats supporting increased prokaryotic microbial activity in the shallow water column. Changes in zooplankton community structure and trophic functions due to climate change may alter the anaerobic microbial activities associated with these zooplankton, affecting nutrient cycling and greenhouse gas production within the fjord. ROSBBY WAVES OR EDDIES: COMPARING QUASIGEOSTROPHIC THEORY WITH SATELLITE ALTIMETRY OBSERVATIONS

Satellite altimetry observations of sea surface height reveal that westward-propagating mesoscale features previously attributed to Rossby waves appear instead to be due to long-lived, nonlinear eddies. Using a reduced gravity shallow water model to diagnose coherency, propagation effects and spectral characteristics, it is shown that the linear Rossby wave description of these mesoscale features is inconsistent with the satellite altimetry observations. Instead, the observations are shown to be largely consistent with the hypothesis that the observed mesoscale signals represent eddies governed by nonlinear quasigeostrophic dynamics. The eddy interpretation is further supported by more recent evidence showing that nonlinear dynamics is necessary to explain the observed covariability between chlorophyll and sea surface height. GAS HYDRATES OBSERVATORY AT MISSISSIPPI CANYON 118

The Mississippi Mineral Resource Institute (MMRI) at the University of Mississippi leads and manages the Gulf of Mexico Hydrates Research Consortium (GOMHRC). The GOMHRC has a goal to research and observe hydrates in situ in the Gulf of Mexico to understand the hydrates stability zone and the factors that cause changes in the stability of hydrates on and below the seafloor over time. The MMRI and the GOMHRC have been conducting research at MCH18 since 2001 and the block was set aside as a research reserve by the Minerals Management Service (now BOEMRE) in 2004. The hydrates research at MCH18 is designed to meet the objectives of the program for hydrate research (NOAA). This presentation will summarize the accomplishments to date of the GOMHRC at MCH18. The accomplishments to date include documentation of hydrate accumulation in fine sediments, successful prediction of the location of hydrates, relationships of faulting to fluid transport and chemistry, time series geochemistry in shallow subsurface and water column, documentation of faunal distribution at the gas-hydrate-bearing zone, and high-resolution mapping of seafloor and features. MONITORING OF THE SOYA WARM CURRENT USING HF OCEAN RADARS, SATELLITE ALTIMETRY, COASTAL TIDE GAUGES, AND BOTTOM-MOUNTED ADCPS

The Soya Warm Current (SWC) is a coastal boundary current, which flows into the Sea of Okhotsk from the Sea of Japan through the Soya/La Perouse Strait, which is a border strait located between Hokkaido, Japan, and Sakhalin, Russia. In order to monitor variations in the SWC, three HF ocean radar stations were installed around the strait in 2003 and continuous monitoring has been conducted. It was shown that the SWC is a seasonal and subseasonal currents and the SWC. The surface transport by the Soya Warm Current shows a significant correlation with the sea level difference along the strait, as derived from coastal tide gauge records. The cross-current sea level difference, which is estimated from the sea level anomalies observed by the Jason-1/2 altimeters and a coastal tide gauge, also exhibits variation in response to along- and across-strait transport and contributes to the sea level difference. Volume transport of the SWC and its seasonal variation were revealed by combination of data from the HF radars and bottom-mounted ADCPs. (Abstract ID 9798)

MARINE ECOSYSTEM-BASED GRADUATE EDUCATION IN ALASKA AS A BEST PRACTICE TO MOVING ECOSYSTEM-BASED MANAGEMENT FROM PAPER TO PRACTICE

At the University of Alaska Fairbanks, graduate education in marine science now includes an interdisciplinary program that is geared to address the unique challenges of marine ecosystem-based management and to understand its implications for society. Graduate students gain a broad background in fishery science and management, ecology, marine science, marine policy, economics, traditional ecological knowledge and anthropology to complement their own specialized expertise acquired through dissertation research and study. The program challenges students to develop innovative approaches to pressing real-world problems. Representative student thesis and dissertation topics include investigating responses of coastal fishing communities to environmental changes, marine mammal fishing interactions, economic valuation of marine tourism and commercial fisheries, impacts of trawling on seafloor communities and habitats, and climate-change impacts on Arctic marine food webs. This interdisciplinary MS and PhD program prepares professionals to solve problems arising at the interface between dynamic environmental and social systems and to address ecosystem-based solutions to critical research and stewardship questions in the sustainable use of living marine resources, skills that are critically needed in today's society. A SIMPLIFIED SPECTROPHOTOMETRIC METHOD FOR MEASUREMENT OF SEAWATER ALKALINITY

A simplified spectrophotometric procedure for analyzing seawater total alkalinity (TA) is presented. This method involves a closed cell, one point titration with a strong acid (hydrochloric acid). The excess hydrogen ion concentration after addition of acid is determined based on spectrophotometric principle using a sulfonaphthalein indicator (Bromocresol purple, BCP) at 25 ± 0.1°C. Absorbance ratios for BCP ((A589 - A750)/(A432 - A750)) were used to quantify the excess hydrogen ion concentration after titration. (H+ [m] as pH of the sample based on Breland and Byrne (1993). Total alkalinity is calculated as TA = m/m0 C - [H+]X (m/m0 + 1) where m0 is the volume of seawater; m and C are the volume and concentration of acid added respectively. The precision of this procedure fell between 0.3 and 1.0 µmolal, which is better than the desired precision of 2 µmolal (+0.1%) for TA measurements. The accuracy of this method fell between 0.6 and 5.0 µmolal compared with seawater measurements using standard open-cell titration procedure. The method has the advantage of fast measurement, limited drift in pH detection, and relative insensitivity to errors in delivering volume of acid and sample. (Abstract ID 9961)

A CLOSURE FOR MESO-SCALE EDDY FLUXES DRIVING ZONAL JETS

Linear instability theory is used to predict the lateral diffusivity K for meso-scale eddy buoyancy fluxes in an idealized channel model featuring eddy-driven zonal jets. The vertical structure and magnitude of K agrees approximately with the non-linear model results. The lateral structure of K from linear theory lacks minima within eddy-driven zonal jets, pointing towards a non-linear mechanism for mixing barriers in the channel model. This effect can be accounted for by a modification of K from linear theory by the kinematic effect of the background flow. Implementation of this closure for K in an eddy mixing framework based on potential vorticity mixing in a zonally averaged model version yields approximate agreement with the zonally resolved version over a certain range of external parameters, in particular with respect to the reproduction of eddy-driven zonal jets. **TROPHIC RELATIONSHIPS OF FIVE SPECIES OF DEMERSAL FISHES IN THE NORTHEASTERN CHUKCHI SEA, 2009–2010**

Fishes in the Arctic are important components of the ecosystem both as predators and as prey. From 2009-2010 fish collections in the Chukchi Sea supported by ConocoPhillips Company; Shell Exploration and Production Company, and StatOil USA E&P Inc., we examined stomach contents and stable isotopes of representative fish species. Five species were selected for diet analysis based on their prevalence on the sampling grounds and because they represented major taxonomic families present in the Chukchi Sea. The selected species were Arctic cod (Boreogadus saida; family Gadidae, cods), Arctic staghorn sculpin (Gymnoscopelus tricuspidis; family Cottidae, sculpins), polar eel pout (Lycodons polaris; family Zoarcidae, eelpouts), stout eelhenny (Anisarchus medius; family Stichaeidae, pricklebacks), and Bering flounder (Hippoglossoides robustus; family Pleuronectidae, flatfishes). Similarity of prey consumed was low within or among areas. Patterns of diet diversity and evenness indices were found among predator species; fish length affected the patterns for Arctic cod. Carbon and nitrogen signatures in the fishes were similar across sites. Some differences were found for all measurements within species and among area, season and length class. (Abstract ID 10576)

VARIABILITY OF FLUORESCENCE-BASED PHYSIOLOGICAL PARAMETERS OF THE PHYTOPLANKTON PHOTOSYNTHESIS IN A TEMPERATE RIVER-ESTUARINE ENVIRONMENT

The application of active chlorophyll a fluorescence in assessing phytoplankton physiology and primary productivity is a major advancement in aquatic ecology, but has not been extensively used in river estuarine environment. This study examined the physiological parameters of photosynthesis-irradiance (PE) curves using the Fast Rate Repetition Fluorometry (FRRF) data obtained in Youngsan river estuary from January to June, 2011. Light limited photosynthetic rate (aFl) was derived as a function of effective Photosystem II (PSII) cross sectional area (ePSII) and maximum efficiency of PSII (Fv/Fm); light saturation parameter (E1K) was determined from the exponential curve fit of Fv/Fm and irradiance; and, light saturated photosynthesis rate at optimal irradiance (PmB) was measured as the product of the bio-optically derived aK and EK. Spatial and temporal variations of fluorescence-based aK, EK and PmB, and instantaneous depth photosynthesis rates were also investigated. The findings of the study could contribute to the development of a better estimate of phytoplankton photosynthesis in a highly dynamic ecosystem like the Youngsan river estuary. (Abstract ID 11309)

THE EFFECTS OF POLYUNSATURATED ALDEHYDES ON THE MICROBIAL COMMUNITIES ASSOCIATED WITH SINKING POM FROM THE SARGASSO SEA DURING A SPRING BLOOM

Polyunsaturated aldehydes (PUAs) are toxigenic compounds produced by diatoms when cell integrity is comprised. The bulk of literature on PUAs has focused on the deleterious effects on diatom grazers. Very few studies have investigated the response of marine microbes to PUA exposure and even fewer studies still have been conducted outside of cultures. Sinking particulate-organic material collected during a bloom in the Sargasso Sea and the associated microbial communities were incubated for 24 h with varying concentrations of a PU cocktail (heptadecanal, octadecanal, and docosanal). PUAs were found to be bioactive, affecting respiration rates, enzymatic activity, intact polar lipid concentrations (a proxy for cell biomass), and the metabolite profile of the microbial community in a dose dependent fashion that suggest allelopathy. Furthermore, these findings indicate that PUAs produced during bloom decline have potential to impact organic matter export. (Abstract ID 11681)

FOUR-DIMENSIONAL VARIATIONAL DATA ASSIMILATION IN THE CALIFORNIA CURRENT SYSTEM AND ITS IMPACT ON ECOSYSTEM STATE VARIABLES

Advanced data assimilation approaches connect temporally distinct observations explicitly through ocean model dynamics allowing longer sequential assimilation cycles than possible with more simple, non-dynamical methods. One example is the incremental, strong-constraint, 4-dimensional variational method which we apply to the California Current System using a 1/10 degree implementation of the Regional Ocean Modeling System. Assimilating sea surface temperature, sea surface height, and subsurface hydrography successfully reduces RMS error with both assimilated and independent data. Using the improved physical state estimate to drive ecosystem dynamics improves the correlation of biogeochemical metrics. However, adjustment of physical fields during each sequential assimilation cycle stimulates vertical nutrient fluxes that fuel overproduction. Such shocks can be reduced through overlapping assimilation cycles or temporal averaging of resultant fields and its effects can be accounted for through direct assimilation of biological fields. In this talk, we discuss all of the above including application of a logarithmic transformation in the assimilation method to ensure positive-definite biological states. (Abstract ID 10879)

THE IMPORTANCE OF BATHYMETRY IN HIGH RESOLUTION LITTORAL MODELING
Characterization and forecasts of the littoral environment are valuable sources of information
for Navy missions including but not limited to ship movement of supplies and personnel and deployment, operation, and retrieval of sensors. Numerical models provide
estimates of dynamic littoral parameters such as current velocities and wave heights and
directions. Model resolutions of O(10 meters) or less are often needed to resolve these
parameters in the shoaling and surf zone regions. In addition, wave evolution and resulting
currents are highly sensitive to bathymetry. The effect of three different bathymetry sources
on results of the Delft3D model will be investigated. The Delft3D model was recently applied
to an area of freshwater Bay, Queensland, Australia for the ‘Taijusalu Saline 2011 exercise. For
the original application, the highest resolution bathymetry source was only O(100 meters).
Additional higher resolution bathymetric data were collected during the exercise—single beam
survey, multi-beam AUV-derived, and satellite-derived. Delft3D hindcasts of the exercise are
being completed using the additional bathymetry sources. A comparison of the Delft3D results
will be presented. (Abstract ID 11293)

MAPPING M2 INTERNAL TIDES USING A DATA-ASSIMILATIVE REDUCED
GRAVITY MODEL
Low-mode internal tide (IT) signals of a few cm are clearly visible in along-track M2 harmonic
constants derived from altimetry data. Although ocean variability causes some temporal
fluctuation, most of the variance in these signals remains phase-locked to the surface tide. We
have developed a scheme for mapping this steady component of IT, by assimilating satellite
data into a reduced gravity (RG) model. A local flat bottom approximation allows decomposition
into modes, with each satisfying modified shallow water equations with spatially varying
coefficients derived from bathymetry and stratification. We implemented this scheme with
minor modifications to the OTIS barotropic tidal data assimilation (DA) system. As an initial
test we generated synthetic data from a 3D baroclinic simulation around Hawaii, sampled as by
the available altimeters, with realistic noise added. We then applied the RG DA to various data
subsets, and compared resulting maps of IT elevations and energy flux to those derived from
the full model 3D fields. The maps accurately reproduce the first mode elevation and energy
flux, when data from multiple satellites are assimilated. We then applied the RG inversion
to select the full set of internal tide signals in the Pacific and Atlantic Ocean, derived from all
available tide gauges and satellite altimetry data from Jason. In the deep ocean results from adjacent patches show excellent agreement at overlaps,
suggesting that global mapping of low-mode IT is practical. We present initial versions of such
maps. (Abstract ID 9970)

THE SPATIO-TEMPORAL DYNAMICS OF THE NITROGEN FLUX ON THE
NORTHERN BENGAUJA HYPOXIC SHELF: A MODEL VIEW
We adopted a 3-D coupled ecosystem model to investigate the spatio-temporal variability of
the physical and biogeochemical nitrogen and oxygen fluxes in the Northern Benguela
upwelling system. This region is characterised by a strong coastal upwelling of nutrient-rich
water that sustains high rates of primary productivity. The estimated mean vertical nitrate
flux into the euphotic zone is 5-20 mmol m$^{-2}$ d$^{-1}$ on the shelf, but even higher in the conspicuous
upwelling cells (30-60 mmol m$^{-2}$ d$^{-1}$). Additionally, nutrient-rich but oxygen-depleted water is
advected from the North by the poleward Angola undercurrent and hypoxic conditions on the
continental shelf are wide spread. We estimated nitrogen fluxes and the biogeochemical oxygen
demand in the water column and the underlying sediments on the continental shelf and the
exchange of nutrients with the adjacent ocean. We paid particular attention to the interaction
between oxygen levels and nitrogen cycling of the aerobic and anaerobic mineralisation
pathways. This study is part of the GENUS-project (Geochemistry and Ecology of the
Namibian Upwelling System), an endorsed project of the Integrated Marine Biogeochemistry
and Ecosystem Research (IMBER). (Abstract ID 10199)

EFFECTS OF ELEVATED CO$_2$ ON PHOTOSYNTHESIS, RESPIRATION,
CALCIFICATION AND SKELETONAL MINERALOGY IN THE RED ALGA
CORALLINA ELONGATA
We investigated the effects of near–future ocean acidification on the red calcareous coralline
algae $C_{.}$f corallina elongata collected from a low–shore tidal pool on the north coast of
Brittany. France. The algae were grown for one month a 1-atmospheric CO$_2$, concentrations, 380, 550,
750 and 1000 ppm. Photosynthesis, respiration and calcification rates were assessed through
measurements of oxygen, pH and total alkalinity fluxes in light and dark using incubation
chambers. Skeletal ratios of magnesium and calcium carbones (MgCO$_3$,CaCO$_3$) were
analysed for different skeletal parts. For comparison, the same parameters were also assessed
in situ under ambient conditions of pCO$_2$. Photosynthesis, respiration and light calcification
were not affected by elevated pCO$_2$. However, dissolution was observed after dark calcification
at elevated pCO$_2$, causing a significant effect on 14h calcification rates. Skeletal MgCO$_3$,CaCO$_3$
ratios did not differ between treatments, indicating no acclimation to more corrosive seawater
by incorporating less magnesium into newly formed skeletal parts. (Abstract ID 10506)

POTENTIAL SEDIMENT EXCHANGE BETWEEN MARSHES AND ADJACENT
SUBMERSED AQUATIC VEGETATION (SAV) BEDS IN CHINCOTEAGUE BAY (MD)
Coastal marshes and submerged aquatic vegetation (SAV) beds within the Chesapeake Bay
have been declining in recent years. Though often located in close proximity, marshes and SAV
beds are not often studied from an ecosystem perspective, especially regarding the exchange of
sediment between them. For example, SAV diebacks can make sandy subtidal sediment available
for landward transport into the marsh, whereas diebacks of marsh vegetation can result in
seaward transport of peaty material to SAV beds. This study examines this potential exchange
in Chincoteague Bay (MD). A transect of cores, one within the SAV bed and four within the
marsh, were analyzed for grain size and organic content; sediment geochemistry were
established with $^{31}$P (half-life 232.3 y). The SAV core was generally composed of sandy and
low organic sediments, with one interval of finer and more organic sediment more typical of
marsh derived sediment. Marsh cores had surficial sand layers up to 20 cm thick, decreasing
landward, likely related to an SAV dieback event in 2005. Accumulation rates in the marsh
generally range 0.2-0.4 cm/y, comparable to sea-level rise. (Abstract ID 11638)

TIDALLY-DEPENDENT STRATIFICATION, SHEAR AND SECONDARY CURRENTS IN YAQUINA BAY ESTUARY, OREGON

Tidal variations in stratification, shear, and secondary currents near the entrance of Yaquina Bay, a shallow estuary on the central Oregon coast, are quantified using current profile and surface and bottom conductivity/temperature time series collected in 2010. The data spanned typical periods of low, medium and high river discharge, Q (mean Q = 1, 5, 18 m³s⁻¹, respectively). Spring tides were distinguished from neap tides. For these data, stratification spanned typical periods of low, medium and high river discharge, Q (mean Q = 1, 5, 18 m³s⁻¹, respectively). Spring tides were distinguished from neap tides. For these data, stratification spanned typical periods of low, medium and high river discharge, Q (mean Q = 1, 5, 18 m³s⁻¹, respectively). Spring tides were distinguished from neap tides. For these data, stratification spanned typical periods of low, medium and high river discharge, Q (mean Q = 1, 5, 18 m³s⁻¹, respectively).

Variations in temperature, ionic strength, pH, and other factors influence partitioning of reactive constituents within the river-littoral zone. This alters the effective particle size spectrum and therefore determines net dispersion, distribution, and transport. In August, 2011, an experiment was conducted in the Pearl River estuary, Gulf of Mexico (GoM), to resolve the size spectrum of suspended matter through the estuary and to investigate factors controlling this distribution. Water samples were collected from the near-surface, mid-depth, and near-bottom of the estuary at eight stations along salinity gradient. Current velocities were determined with a downward-looking ADCP. Particle size distribution in each sample was determined in the laboratory using a Zeta-sizer to evaluate the nm-range size fraction and a nanoparticle tracking analyzer (NPA) to evaluate larger (> 30 nm) fractions, suggesting that algal/phytoplankton or competition interactions were enhanced with nitrogen enrichment. BACTERIAL COMMUNITIES ASSOCIATED WITH THE PELAGIC TUNICATE D. GEGENBAURI AND THEIR FECAL PELLETS: WHAT IS THEIR ORIGIN?

Fecal pellets of pelagic zooplankton represent a major component of the vertical flux of organic carbon in the open ocean, and thus a potential sink in the global carbon cycle. The ultimate fate of these pellets is subject to their colonization and degradation by heterotrophic bacteria, yet little is known regarding the source or activity of these bacterial communities, especially those associated with gelatinous zooplankton species. To address this question we are investigating the origin of heterotrophic bacterial communities associated with the fecal pellets of the pelagic tunicate Doliolitta gegenbauri. Laboratory reared D. gegenbauri gonozoides were fed diatom cell cultures or freshly collected plankton-rich intrusions water from the South Atlantic Bight continental shelf. The relative abundance and composition of bacterial communities associated with food particles, full gut animals, stavged animals, and fecal pellets was determined based on 16S rRNA targeted qPCR data and clone library sequencing, respectively. The surprising paucity of bacteria associated with the animals themselves suggests that D. gegenbauri do not harbor endemic gut microbial communities and that the colonization of pellets occurs post egestion. UREA IN CENTRAL MAINE COASTAL WATERS: CONCENTRATIONS AND INTERACTIONS WITH ALEXANDRIUM FUNDYENSE IN NATURAL MICROBIAL POPULATIONS

Urea use in fertilizers has increased in past decades, suggesting that agriculturally derived urea may be transported into coastal Maine waters where it is a potential nutrient source for blooms of Alexandrium fundyense. This study examined 1) urea concentration in the St. George River Estuary before and after a large rainfall event, and 2) the influence of nitrogen form, including urea, on growth of natural coastal microbial populations in biosalvages with and without added A. fundyense. A significant increase in urea concentration post-rainfall was documented at only one site in the lower river, suggesting that inputs may occur only immediately after fertilization, that in situ nutrient cycling occurs rapidly, or that urea inputs are minimal. In biosalvages, A. fundyense growth rate did not vary with nitrogen form, however, A. fundyense cell yield increased with all nitrogen additions, suggesting urea was bioavailable to A. fundyense. Alexandrium fundyense differentially influenced coincident microbial populations in all nitrogen enrichments, stimulating smaller (0.7–3 µm) chlorophyll fractions, and inhibiting larger (> 30 µm) fractions, suggesting that algal/phytoplankton or competition interactions were enhanced with nitrogen enrichment. (Abstract ID 10924)

AIRBORNE SENSING OF SEA SURFACE TEMPERATURE PATTERNS IN OIL COVERED WATERS

Airborne thermal infrared (IR) imagery is used to measure sea surface temperature (SST) patterns in oil-covered waters in the Gulf of Mexico during the 2010 Deep Water Horizon (DWH) oil spill. While previous studies of oil spills emphasized visible and synthetic aperture radar (SAR) imagery there are some significant advantages to using IR imagery. They include minimal oil film thickness detection limits, thermal signature variability of different oil film signatures during daytime solar heating input, and nighttime oil spill detection/monitoring for which aerial thermal imaging represents a uniquely practical solution. The oil system was used operationally throughout the DWH spill response to aid in response and recovery. Since calibrated, absolute IR images are useful for actual oil thickness computations we have also used the Ball Experimental SST (BEST) radiometer to make preliminary airborne measurements over the Gulf of Mexico in July 2010. In these 2D thermal infrared swaths, the relative contrast can, by itself reveal the locations of the thickest of oil patches. The BEST is based on a microbolometer and carries 2 black bodies for onboard calibration of the imagery. (Abstract ID 9893)

EVALUATION OF DIRECT COVARIANCE AIR-SEA CO2 FLUX MEASUREMENTS IN THE COASTAL OCEAN

Field observations of ocean-atmosphere CO2 fluxes using the direct covariance method have a history of limited success that to date has mostly depended on the varied quality of open-path infrared gas analyzer measurements. This quality is in turn related to the low signal-to-noise environment for CO2 variability within the moist marine atmospheric boundary layer. Several recent advances in post-processing of these CO2 observations suggest that the reliability and capability for such gas flux subsystems may be poised for expanded application. This study will present results from several field deployments of eddy correlation packages in the coastal ocean with the objectives to assess viability and reliability of collecting long-term direct covariance sea flux measurements in the Gulf of Maine region. This shelf sea location provides conditions of variable and large air-sea gas disequilibria as well as a large dynamic range in wind and wave conditions. Systems were operated on both a discus buoy and island tower site for multi-month periods in 2009 and 2011. Issues of motion correction, accurate high rate CO2 measurements, and derived fluxes will be addressed. (Abstract ID 10213)

CHANGING OCEANS, CHANGING ROLES: THE CHALLENGES AND OPPORTUNITIES FOR SCIENTIST COMMUNICATORS IN THE 21ST CENTURY

As the rate of change in the ocean increases through the next several decades, the need for scientists to help society understand and confront these changes also will grow. But navigating the challenges faced by scientists who seek to communicate across a cultural divide at the science-to-policy interface requires training beyond what traditional academic models provide. In addition, many scientists lack a conduit for understanding the needs of policymakers in terms of specific policy relevant scientific and technical expertise. COMPASS works at the intersection of the worlds of science, journalism and policy to support scientists in "escaping the ivory tower," helping them give their research real-world impact. Functioning as a boundary organization, COMPASS helps scientists connect what they do in ways that reach media and policy audiences more effectively – using tools of science synthesis, policy outreach, and communication training. This talk will use case studies from fields such as marine biology and ecology, climate change, and ocean acidification, in which scientist leaders connected their science to a dynamic policy landscape in ways that had lasting impact. USE OF IN-SITU OPTICAL SCATTERING AND FLUORESCENCE MEASUREMENTS FOR THE REAL-TIME DETECTION OF DISPERSED OIL IN WATERS NEAR THE DEEPWATER HORIZON OIL SPILL.

Vertical and horizontal profiles of bio-optical measurements were collected on several cruises between May and August 2010. The profiles, which included chlorophyll and CDOM fluorescence as well as scattering measurements, were made both near the Deepwater Horizon oil spill and in Gulf of Mexico waters unlikely to be contaminated by the oil spill. Data from the vertical profiles support the hypothesis that below the near-surface layer (~50 m), a combination of chlorophyll fluorescence and single-angle scattering measurements allows estimation of anomalous scattering, and thus provides a real-time indication of dispersed oil in seawater. The data from the profiles indicate that this scattering anomaly approach is more sensitive to the presence of dispersed oil than detection solely on the response of a typical single-channel CDOM fluorometer. Measurements of near-surface bio-optical properties collected using continuous flow-through sampling provided insight into the spatial variability near the Deepwater Horizon oil spill, though the complexity of the near-surface bio-optical environment and paucity of appropriate hydrocarbon and baseline measurements increase the ambiguity of the near-surface observations’ interpretation. (Abstract ID 11839)

THE ROLE OF LATERAL FLOWS IN DRIVING TIDAL PERIOD ESTUARINE STRATIFICATION

Stratification in estuarine systems plays an important role in a number of physical and biogeochemical processes. We studied tidal period variability in stratification based on moored data from the Delaware River estuary. In the classic theory of tidal straining (Simpson et al 1990) stratification is enhanced on ebb relative to flood due to the vertical shear acting on along-channel gradients. On the other hand many estuarine systems exhibit strong lateral density gradients. Therefore we investigated how cross-channel flows affect intra-tidal variations in stratification based on data from a mooring array deployed in the Delaware River/Bay over a 3 month period. Analysis of the data indicated that the Delaware Bay strays away from the classic theory because it becomes more stratified on the flood instead of the ebb. It was also observed that along- and cross-channel stratification of the density field were around the same order of magnitude and therefore the cross-channel circulation appears to play an important role in tidal period variability in the stratification of the Delaware Bay. (Abstract ID 10096)

A NEW CENSUS OF EDDIES IN THE WESTERN MEDITERRANEAN FROM SATELLITE ALTIMETRY

Eighteen years of weekly SLA merged maps in the Western Mediterranean are analyzed using the new method proposed by Chelton et al. (2011) to identify and track mesoscale eddies. The highly productive Chukchi Sea shelf is a complex gateway into the Arctic, on which climate variation may have a profound impact. We examined summer zooplankton community structure in the Arctic waters between Alaska and Russia from the Bering Strait northward to Wrangel Island during 2004, 2009 and 2010 within the on-going RUSALCA (Russian-American Long-term Census of the Arctic) program. We also accessed secondary production by conducting egg production experiments on some of the most abundant copepod genera (Pseudocalanus spp., Metridia spp.), which have both Arctic and Pacific members. The total abundance and biomass of holozooplankton varied significantly across the area and between the years, averaging 3500 ind m-3 and 42 mg DW m-3 in 2004, 8250 ind m-3 and 78 mg DW m-3 in 2009, and 9700 ind m-3 and 69 mg DW m-3 in 2010, all based on 150 µm nets collections. The species composition also varied significantly; we encountered a total of 68 holoplanktonic species in the region, as well as a wide variety of meroplankton, which also contributed notably to community biomass and abundance. In contrast, temperature-adjusted reproductive rates showed little difference between years. Several major assemblages of zooplankton were identified using multivariate analysis and tied to distribution of the water masses present in the region. (Abstract ID 12035)
than the cyclones. The propagation speeds and direction show a wide range of values without a clear preferred direction, although there is a certain west-east dominance. The temporal evolution of the weekly number of eddies is also examined presenting a small trend modulated by intraannual and interannual variability. These are preliminary results that need to be further developed to understand the dynamical processes that can explain the observed variability. Future work also includes performing a sensitivity analysis on the parameters of the method as well as improving the eddy identification close to the coast. (Abstract ID 11019)

PARTICLE CAPTURE BY BIOLOGICAL COLLECTORS IN AQUATIC SYSTEMS

The term particle capture refers to the physical process by which suspended particles come into contact with biological structures (‘collectors’) and adhere to the collector’s surface. One important occurrence of particle capture in aquatic ecosystems is the adhesion of particles over vegetation surfaces. This phenomenon defines the filtration and water purification capacity of vegetated wetlands. Particle capture is also of significant ecological importance in marine ecosystems; in particular, it controls the efficiency of seagrass polination, coral and benthos feeding, and larval settlement. Despite its fundamental ecological importance, particle capture in aquatic systems remains poorly understood. In order to better understand particle capture dynamics, a numerical model was used to determine the two-dimensional fluid flow and the motion of suspended particles around a single cylindrical collector. Accurate expressions for particle capture by inertial impaction and direct interception were obtained which compare very well to experimental data. As prediction of capture efficiencies for aquatic ecosystems is extremely limited, the obtained expressions are a very valuable tool for evaluating particle-collector interactions in aquatic ecosystems. SUSPENDED SEDIMENT CONCENTRATION AND OPTICAL PROPERTY OBSERVATIONS OF MIXED-TURBIDITY, COASTAL WATERS THROUGH MULTISPECTRAL OCEAN COLOR INVERSION

Multispectral satellite ocean color data from high-turbidity areas of the coastal ocean contain information about the surface concentrations and optical properties of suspended sediments and colored dissolved organic matter (CDOM). Empirical and semi-analytical inversion algorithms published to date are insufficient to retrieve this information when suspended sediment concentrations exceed order 10^6 g m^-3. However, this is in part because high-gain “ocean” bands on orbiting sensors saturate over bright, turbid waters, and because of the difficulty of obtaining satellite/in situ field match-ups under high-turbidity conditions that persist for short periods of time. We present an alternative semi-analytical method that simultaneously utilizes high- and low-gain bands on the MODIS/Aqua sensor, and is tuned for coastal Louisiana using mass-specific inherent optical properties of local suspended sediments. The multispectral inversion method is applicable to both moderate and high turbidity conditions. We discuss the sensitivity of the algorithm to optical model assumptions, and compare inverted sediment and CDOM IOPs from MODIS/Aqua imagery to published data for the study region. STUDENTS OF TEACHER RESEARCHER EXPERIENCES (SOTRE)

Mrs. Eubanks is the middle school teacher at St. Mark Catholic School and has taught all of the students excited for science. She has helped involve students in many different programs sponsored by the National Oceanographic and Atmospheric Administration (NOAA) and PolarTREC (Teachers and Researchers & Exploring & Collaboration). Being a part of these programs gives students special privileges such as being able to track tagged sharks, follow daily journals written on location, participate in live time webinars and take part in cross-continental experiments. In addition, the contacts, made through Teacher Researcher Experiences (TRE) give students an added set of resources for future reference. When doing experiments for class, Mrs. Eubanks can put students in contact with other scientists she has met and he offers the students a unique opportunity to work together with real scientists on school projects. Being a part of these relationships with NOAA, Polar TREC, and research scientists actively working in their fields of study, provides students, Students of Teacher Researcher Experiences (SOTRE), the ultimate scientific learning experience. DEEP TIME FORAMINIFERA Mg/Ca PALEOTHERMOMETRY – ACCURATELY CORRECTING FOR SECULAR CHANGES IN THE Mg/Ca RATIO OF CENOZOIC SEAWATER

Mg/Ca-derived temperatures from foraminifera represent one of the best methods of oceanic paleotemperature reconstruction. However, besides temperature, a major control on the Mg/Ca ratio of foraminiferal calcite is the Mg/Ca ratio of seawater. This has undergone secular variation over the Cenozoic such that if the total range of Cenozoic Mg/Ca seawater values are considered this influence is approximately equal in magnitude to that resulting from temperature. Mg/Ca paleothermometry is furthermore complicated by uncertainty regarding seawater Mg/Ca values for climatically important time periods, where paleoceanic temperature reconstruction is a priority. We present the first Mg/Ca-derived temperatures (using highly spatially-resolved LA-ICPMS analysis) from foraminifera to be accurately corrected for paleoseawater Mg/Ca and extend our results to constrain the Mg/Ca value of Eocene seawater: Differences between our conclusions and previous studies arise from earlier assumptions regarding Mg/Ca variation with changing seawater Mg/Ca. We have also indirectly assessed the Mg/Ca seawater-Mg/Ca calcite relationship of species for which this aspect of Mg/Ca paleothermometry has not been directly studied. This allows us to discuss the implications of our findings for the Cenozoic benthic foraminifera Mg/Ca-temperature curve. (Abstract ID 11151)

IMPACTS OF PLANETARY WAVES ON THE BERMUDA ATLANTIC TIME SERIES STUDY

Data from the Bermuda Atlantic Time-series Study (BATS) and satellite-based altimetry measurements are analyzed with the aim of better understanding the effects of westward propagating planetary waves on the vertical structure of the water column. Isopycnal displacement calculated as the deviation from the mean potential density profile between October 1988 and June 2011 reveal amplitudes of ±200m throughout the water column with maximum displacement between 1500-2500m. Band pass filtering (37 to 410 days), intended to distinguish isopycnal displacements with sea surface height anomaly (SSHa) filtered to isolate westward propagating features of the same period shows a strong coherence between these two fields. At the BATS site significant correlations between isopycnal displacement and SSHa are found between 100m and 1500m (R between 0.2-0.5). We argue that much of the isopycnal displacement at BATS is driven by westward propagating planetary waves and discuss implications of these dynamics as a mode of nutrient flux into the euphotic zone. DISSOI LVED INORGANIC CARBON VARIABILITY IN THE SOUTH ATLANTIC SECTOR OF THE SOUTHERN OCEAN

In February/March 2008 and February/March 2009, hydrographic cruises were completed along Drake Passage (WOCE section S9), and along 30°S from the African continent to Antarctica (WOCE section S16). These hydrographic cruises were compared with previous cruise data from 1990 and 1996, respectively. The existing GLODAP and CARINA calculated
A REGRESSION MODELING APPROACH FOR STUDYING CARBONATE SATURATION STATES ON THE NORTHERN GULF OF ALASKA SHELF

The northern Gulf of Alaska shelf experiences manifestations of ocean acidification that have only been assessed on seasonal and annual time scales. Little information is available to resolve higher frequency variability in this region. We present a multiple linear regression modeling approach using a subset of hydrographic data collected along the North East Pacific (NEP) Global Ocean Ecosystem Dynamics (GLOBEC) Seward Line. The empirical algorithms predict dissolved inorganic carbon (DIC) and total alkalinity (TA) using observations of temperature, salinity, pressure and nitrate from the surface to 1200 m, with R2's > 0.97 and RMSE errors of 14 µmol kg-1 (DIC) and 11 µmol kg-1 (TA). Carbonate saturation states were then calculated from predicted DIC and TA. We applied these algorithms to a data set from a 24-hour glider occupying the inner shelf conducted in June 2011, and a SeaSoar data set collected during a 2003 NEP GLOBEC mesoscale mapping survey. Predicted saturation states provided valuable insights into the variability from tidal forcing and mesoscale eddies. This work is similar to recent studies aimed at predicting acidification in coastal margin settings, albeit demonstrates a nitrate-based approach applied to high-latitude data collected from platforms capable of high-frequency measurements. (Abstract ID 9433)

ADVANCES IN INCORPORATING BIO-OPTICAL DATA IN LONG TERM OBSERVING SYSTEMS: CHALLENGES AND SOLUTIONS

The Australian Integrated Marine Observing System (IMOS) is measuring bio-optical properties of the coastal ocean on an unprecedented scale. IMOS has developed a network of nine National Reference Stations across Australia's coastal seas where we measure physical and optical properties (fluorescence and backscatter) at 15 min intervals using WET Labs WQMs. Groundtruthing of the mooring data is done with monthly shipboard sampling using CTD profiles and biochemical analysis of water samples. IMOS data is made available to the scientific community through a central data repository. The continental scale of IMOS combined with the volume of data brings new complexities from the operational level through quality control and data analysis, particularly because we are combining optical data from multiple platforms and sensors. Here we use a near continuous 2-year data record from Sydney, Australia to examine the oceanography of this dynamic region. We investigate the covariance between optical signals and other sensor records as a way of estimating the quality of the timeseries data and we introduce stringent pre and post deployment checks to ensure the integrity of the long term data set. (Abstract ID 12589)

HIGH-RESOLUTION SEDIMENTARY RECORD OF DIATOM PRIMARY PRODUCTIVITY OF THE LATEST 60 YEARS IN YANGTZE RIVER ESTUARY AND ITS RESPONSES TO GLOBAL CHANGES

Based on the data of sedimentary biogenic silica (BSi) in a gravity core collected in the Yangtze River estuary and the using of annual sedimentary layer dating method, high-resolution record over the latest 60 years was established. The BSi record shows periodic changes of about 20 yr, 11 yr, 3 yr and 1 yr cycles, accompanying with a gentle increasing trend. The 20 yr and 11 yr periods are consistent well with the sunspot magnetic property cycle and sun spot number cycle. The 1 yr period is due to seasonal fluctuations controlled by the East Asian Monsoon. And the cycle of 3 yr with gentle increasing trend agrees with the North Pacific decadal oscillation (PDO). Contributions of seasonal process, PDO, and sunspot activities to total BSi variance are about 13%, 30%, and 25%, respectively. Meanwhile, increases of nutrients inputs, or decreases of sediments discharges, which are from increasing anthropogenic activities, are within the surface ocean of the Antarctic Circumpolar Current (ACC) fronts. Changes in the Redfield ratio of nitrate, phosphate and dissolved inorganic carbon (DIN) are examined for signals of biogeochemical and anthropogenic change. A comparison of Redfield ratios for each section shows no phosphate change, a weak nitrate increase and a greater increase in DIC. (Abstract ID 11029)

**QUANTIFYING THE CONTRIBUTION OF MESOSCALE ANTICYCLONES TO THE IRMINGER SEA HEAT AND FRESHWATER BUDGETS**

The Central Irming Sea (CIS) mooring observed properties of two water masses from 2002 to 2009: Irming Sea Water (ISW) and Labrador Sea Water (LSW). In the ISW, the heat balance is dominated by surface and lateral fluxes. The freshwater budget is controlled by lateral and vertical fluxes. Lateral fluxes consist of anticyclonic eddies in the CIS basin which have anomalously warm, salty water. They form from the Irming Current at the Reykjanes Ridge, propagate into the CIS basin, and are mixed into the CIS during winter mixing. Eddy seasonal average temperature and salt contributions are estimated using a combination of satellite altimetry and mooring statistics. They are compared with surface heat and freshwater fluxes. Results show that on a seasonal timescale, the surface flux controls the heat variations in the ISW; however, over the 7-year timeseries, the total heat contribution from the anticyclones nearly balances the net surface heat flux. This suggests that over the long term, these eddies play a significant role in balancing the heat budget in the CIS. A linear increase in salinity is observed in the ISW and LSW over the 7-year period. Using only surface and eddy freshwater contributions, the average yearly ISW salinity is computed. The resulting trend is almost identical to the observed salinity trend in the ISW, suggesting that the salt transport due to the anticyclones can explain the salinity increase observed in the ISW layer. **TIME REAL CAL/VAL WITH SATELLITE VALIDATION NAVY TOOL (SAVANT)**

A new capability for daily match-up of satellite products and in situ data streams enhances inter-satellite consistency of ocean color products. SAVANT enables an "end to end" capability to validate multiple satellites (MODIS, MERIS, VIIRS, GOCC) from sensor to end products. SAVANT includes a real time, web-driven SQL database, which integrates 65 satellite products (LW/10P, metadata atmospheric models, flags, solar angles, etc.) and in situ data (water, buoy, glider and ship data). SAVANT allows for evaluation of top of atmosphere (TOA) radiance monitoring in several coastal and ocean locations, operational algorithms with real time in situ matchups, and cross-calibration of upcoming sensors (VIIRS) with heritage missions (MODIS, MERIS). Presently, CAL/VAL activities are performed at 25 areas around the world. These “Golden Regions” represent different types of atmospheric and water types: AERONET-OC coastal sites, optical buoys (MOBY, Bousole) in blue waters, time series studies (HOT, BATS, PNB), regions where ship measurements are being collected and six oligotrophic ocean regions. These regions have been used for comparison and inter-calibration of ocean color sensors. (Abstract ID 11090)

**NONLINEAR INTERNAL WAVES IN THE SOUTH CHINA SEA DURING WINTER 2010–2011**

In a pilot study of nonlinear internal wave (NLIW) generation and evolution, pressure-recording inverted echo sounders were deployed in Luzon Strait and the South China Sea (SCS) during 09/2010–06/2011. Acoustic echo times at 6-second intervals were retrieved at 3 sites from November 2010 to April 2011 (2 in Luzon Strait and one in the SCS). The observations reveal energetic NLIWs during the winter months, suggesting that lack of remotely-sensed NLIWs in winter is due to wind-induced surface roughness obscuring surface NLIW signals. Wave packets with relatively weak NLIWs were also observed from mid-November to mid-December 2010 and from mid-February to mid-March 2011. Comparisons with data-assimilated HYCOM outputs reveal that the weak NLIWs occurred when the Kuroshio intruded into the SCS or the weakened Kuroshio modified stratification in LS. Numerical simulations and a simplified 2-D internal wave model will be used to explore the impacts of background circulation and stratification changes on the evolution of NLIWs in the SCS. **COASTAL CONNECTIONS: ADVANCES IN THE UNDERSTANDING OF THE INTERACTION OF FLUVIAL AND MARINE SYSTEMS**

Rivers are the primary delivery mechanism for sediment and dissolved material to the coastal ocean. A more clear characterization and quantification of the controls on contemporary delivery coupled with continued exploration of the sedimentary record have lead to tremendous growth in our understanding over the past few decades. In this review, we seek to present an overview of the growth in understanding across multiple temporal and spatial scales of the flux and fate of material from land to the ocean by examining the contributions of Professor John D. Milliman, his students and his collaborators. For decades, John Milliman has lead fellow marine and terrestrial scientists in collaborations to further understand the fluvial delivery, the marine distribution processes and the record that is stored in both terrestrial and coastal sedimentary records to better understand the complex linkages between land and sea. (Abstract ID 12836)
THE EFFECT OF WIND ON CURRENTS IN THE COLUMBIA RIVER

We have deployed an X-band Doppler radar over the north channel of the Columbia River (under the Astoria-Megler bridge) to measure along-channel surface currents. A six-month-long record of these currents indicates that, after removing tidal effects, the residual mean current is always toward the river mouth (as expected), and is highest when the wind direction is toward the mouth of the river and lowest when the wind direction is away from the mouth. Furthermore, the change in current between these two conditions increases with wind speed. This change is much larger than can be explained by a surface drift layer. Therefore we suggest that the current through the whole water column depends on the wind. This supposition is supported by the fact that the stage of the river measured at Astoria, normalized by the upstream discharge measured at the Beaver Army Terminal, is higher for winds toward the mouth and lower for winds away from the mouth. (Abstract ID 10433)

A SURVEY OF WAVES ON SUBSEASONAL TIME SCALES IN THE TROPICAL PACIFIC OCEAN

Data from satellite altimetry and from the TAO/TRITON mooring array are used to characterize and discuss wave-like variability in the tropical Pacific Ocean at periods of days to a few months. The goal is to provide a synthesis view of the variability on subseasonal time scales, with emphasis on an interpretation in terms of wave dynamics. At the higher frequencies (periods of 2-14 days), there is clear evidence for the presence of several basin-scale equatorial wave modes, including Yanai waves and inertial-gravity waves associated with baroclinic modes one and two. At the lower frequencies (periods of 1-2 months), the variability of sea level is dominated by equatorial Kelvin waves and tropical instability waves, although variability resembling barotropic Rossby waves and equatorial Rossby waves is also present. (Abstract ID 11666)

A ROMS-based data-assimilating ocean forecast system is being developed as part of the GOMEX-PPP (Pilot Prediction Project), which seeks to evaluate and demonstrate numerical model-based operational predictions of the circulation of the Gulf of Mexico. The primary drivers of this circulation are the Loop Current and its associated Loop Current eddies. The data assimilation component uses a multi-scale 3DVAR methodology which is flexible enough to allow assimilation of many different types of data and is also computationally efficient enough for real-time operations. Results produced by the system for 2010, including nowcasts and hindcasts for the period of the Deepwater Horizon oil spill event, will be presented. Real-time 3-month forecasts were begun in September 2011 and consist of a set of forecasts performed once every two weeks during the period September through December 2011. The skill of these forecasts will be evaluated with an emphasis on the variations in the Loop Current and associated eddies. In addition, the performance of ensemble forecasts - both traditional and multi-model - for this period will be evaluated. (Abstract ID 12422)

AN AUTONOMOUS DISSOLVED INORGANIC CARBON MEASUREMENTS ON A MOORED BUOY

The temporal and spatial richness of ocean carbon measurements has increased dramatically over the past 30 years; however, the constraint on even richer data sets has largely been due to sluggish technological advancement in this area. More recent interest in surface ocean biogeochemistry, due to the growing concern with ocean acidification and future ocean carbon cycling, has prompted calls for instrument advancement in the area of ocean carbon cycle observations. In response to the need for progress in this area, we have developed a robust dissolved inorganic carbon (DIC) sensor prototype. Building off of the NOAA Pacific Marine Environmental Laboratory moored pCO2 system (MAPCO2; now commercially available through the Battelle Memorial Institute), this DIC sensor uses the proven technology of infrared detection of CO2 in a gas stream. In this application we acidify a known volume of seawater, and quantify the CO2 that is evolved from the sample. This fast and reliable technique has been used routinely in shipboard systems to measure DIC, but has not previously been adapted for robust, long-term, autonomous DIC measurements on a mooring. Results from our first deployment of the moored DIC instrument prototype are presented here. (Abstract ID 11706)

PATHWAYS TO OCEAN SCIENCES: BROADENING PARTICIPATION IN OCEAN SCIENCES REU PROGRAMS

Increasing the number and diversity of students who successfully pursue careers in Ocean Sciences is key to addressing the growing demand for professionals in our fields who genuinely understand and realize a contribution to cutting-edge research. Summer research programs for undergraduates play a critical role in this process by creating environments where students
can develop the strategies and professional skills necessary to pursue meaningful careers in various STEM fields and by supporting students as they "bridge" between undergraduate and graduate studies. Within the framework of a diversity briefing illuminating the context behind efforts to broaden participation, the Institute for Broadening Participation (IBP) will provide a short overview on the current state of diversity in the Ocean Sciences community in general and the NSF Ocean Sciences REU community in particular, as well as offer a shared resource pool of studies, references, practical tools and strategies focusing on broadening the participation of women and underrepresented groups in higher education. IBP has been supporting diversity by fostering an on-going exchange of ideas and resources between students, faculty and administration since 2002. Their web portal, www.pathwaystoscience.org, provides easy access to many resources that support students in successful careers in the STEM fields, and support faculty and administrators in enhancing their efforts to increase diversity. ESTIMATING GLOBAL OCEAN CARBON TRENDS USING IN-SITU pCO2 OBSERVATIONS, 1981-2010
Ocean carbon uptake significantly modulates the atmospheric CO2 levels, slowing the rate of anthropogenic change. The global ocean carbon sink appears to be changing, but it is difficult to distinguish the degree to which these changes are driven by anthropogenic climate warming as opposed to natural decadal timescale variability. Recent studies of the North Atlantic carbon cycle suggest conflicting flux trends: data-based extrapolations report a declining sink (Schuster et al. 2009), while models with suggested an increasing flux (Ullman et al. 2009). Through analysis of the Takashada pCO2 dataset in the North Atlantic, McKinley et al. (2011) find that changes previously termed “trends” were more likely driven by decadal timescale climate variability rather than anthropogenic climate change. However, we do find that anthropogenic warming is beginning to reduce carbon solubility on multi-decadal timescales in the subtropical gyre of the North Atlantic, which is consistent with recent modeling results (Le Quere et al. 2010). Using the vast, newly updated, in-situ pCO2 dataset and a similar methodology to McKinley et al. (2011), we assess global ocean pCO2 trends over recent decades for the major ocean basins, specifically focusing on results in the Pacific for this presentation. We present results for changes in carbon uptake over varying timescales and also assess mechanisms, particularly the degree to which warming is limiting carbon uptake. (Abstract ID 11749)

STUDYING TROPHIC COMPARTMENTS OF EUKARYOTIC MICROBIAL FOODwebs USING A THYMIDINE ANALOG AND ENVIRONMENTAL DNA SEQUENCING
Eukaryotic microbes are a critical trophic link between prokaryotes and higher trophic levels, playing an important role in ecosystem function. Advances in molecular ecology have revealed a high taxonomic diversity of uncultured eukaryotes from aquatic environments. In an effort to determine the ecological role of these microbial eukaryote taxa, we added BrdU-labeled bacteria to culture bottles of environmental water samples. The bottles were then incubated to allow bacteria to be ingested and the BrdU label to become incorporated; the samples were filtered and whole DNA was extracted. BrdU-labeled DNA was isolated from whole DNA using immunoprecipitation. We analyzed the samples with both PCR-DGGE and amplicon pyrosequencing using universal eukaryotic primers. Our results show that the BrdU-labeled community is a distinct subset of the respective whole community. Certain cryptophyte, chrysophyte, and ciliate taxa in particular show labeling with BrdU. We suggest that these taxa be considered putative bacterivores and that this method has the potential to reveal actively feeding members of the microbial community. (Abstract ID 9982)

HIGH-RESOLUTION MODELING OF CIRCULATION ALONG THE US WEST COAST
To study coastal and interior ocean dynamical interactions, a 2-km resolution model based on the Regional Ocean Modeling System (ROMS) is applied in the domain occupying an area in the north-east Pacific Ocean (35N–55N, 134W–120W). Initial and boundary conditions are based on the HYCOM-NCODA global 1/12th degree analysis. Atmospheric forcing is formed based on the North American Mesoscale Forecast System (NAM). Our study is initially focused on the fall transition and winter 2008-09, including formation and propagation of large-scale anticyclonic eddies, near-surface boundary layer dynamics during strong storms, and connectivity of the wide-scale eastern boundary California Current (flowing to the south) and the coastal current (flowing to the north, associated with seasonal downwelling). Both the HYCOM and the nested ROMS solutions are compared against available satellite SSH, SST, and in-situ glider and mooring data. Potential difficulties nesting our model in a data assimilated product include consistency of boundary fluxes and the area-averaged SSH variability and aliased high-frequency modulations extending to depth. VERTICAL STRUCTURE OF TURBULENCE UNDER SURFACE BREAKING WAVES
Observations of the vertical structure of turbulence under breaking waves in a natural surfzone are sparse. In the surfzone, both the surface (via breaking waves) and the bottom (through bed-generated shear) can be significant turbulence sources. Here wave, current, and turbulence observations from the IB90 experiment (Fall 2009 at Imperial Beach CA) are presented. A cross-shore array spanning 150 m of 5 tripods were deployed with rapidly sampling pressure sensors, ADV current meters, thermistors, and dye-measuring fluorometers. In addition, in the mid-to-out surfzone an additional frame (denoted VS, vertical stack) with a vertical array of 3 ADVs, thermistors, and fluorometers spanning from within 0.2-1.6 m above. A nearby vertically profiling Aquadopp ADCP measured the vertical structure of the mean flow. In addition to wave and current statistics, turbulence statistics such as the turbulent dissipation rate, Reynolds stresses, turbulent vertical temperature flux, and dye tracer fluxes are estimated. From these observations turbulent energetic balances are examined to determine the contribution of bottom boundary layer turbulence relative to breaking-wave generated turbulence in the surfzone. SPACE-TIME STATISTICS AND SPECTRA FROM STEREO MEASUREMENTS OF GRAVITY WAVES
Classical time series measurements of the ocean surface displacements at a fixed point P of the ocean are generally retrieved from wave gauges, ultrasonic instruments or buoys. Despite being very informative and widely acquired routinely, these data bring along low information to provide accurate predictions of the space-time wave dynamics and of the associated statistical and spectral properties over an area centered at P. As an alternative, an approach based on a stereo camera view would allow retrieving both spatial and temporal data. To prove this, an application of the Wave Acquisition Stereo System (WASS) is presented for the analysis of offshore video measurements of gravity waves over large areas of approximately 1100 m2. WASS was deployed at the oceanographic platform Acqua Alta in the northern Adriatic Sea, Italy. WASS analysis yielded accurate estimates of the sea surface and its associated directional spectra. Furthermore, the expected largest wave height over an area is estimated via Euler characteristics. It is found that waves over an area are larger than those expected at a given point in time. EDUCATIONAL COLLABORATION AND RESEARCH BETWEEN ISLAND, COASTAL, AND ARCTIC INSTITUTIONS.
We present the results of an ongoing educational and research collaboration between the University of Hawaii, University of Puerto Rico, University of Alaska, the Stevens Institute (New Jersey), and future partners from other nations/states. Students from these institutions have built, tested and deployed passive acoustic recording systems and have shared their data as part of a collaborative research effort. Data are collected using identical systems and field collection protocols enabling direct analysis and comparison from various island, arctic and mainland coastal environments. The student-led experiments address real scientific questions and use research-grade equipment and analysis tools. Examples of projects include measuring background noise levels of coastal ocean environments and detect biological, physical, and anthropogenic changes. The program has educational initiatives that have sent students to summer programs at the Stevens Institute in Hoboken, New Jersey. We are currently organizing a program with the US Coast Guard to allow students who have been trained through the program in harbor protection to participate in multi-day Coast Guard deployments. (Abstract ID 12800)
This study focuses on the pronounced interdecadal AMOC variations simulated by many coupled climate models. Models, we conduct a stability analysis of a realistic ocean GCM and show the existence of an interdecadal, weakly-damped mode of oscillation centered in the northern Atlantic and related to ocean dynamics. The mode period is approximately 24 years and its manifestation is evident in the westward propagation of temperature anomalies in the upper Atlantic ocean. These temperature anomalies affect the ocean density field and hence ocean circulation (especially within the Subpolar Gyre). The most powerful mode to excite this mode is via optimal initial perturbations in surface temperature and salinity centered off the eastern coast of Greenland and Canada, south of the Denmark Strait. Simple estimates show that moderate changes in surface temperature or salinity in this region can lead to AMOC variations on the order of 10–20%. Next, we consider the IPSL coupled model that has the same ocean component and extends AMOC variations with a period close to that of the least-damped mode in the ocean-only GCM. We show that the mechanism of these variations in the coupled model is the excitation of the exact same oceanic mode by the atmosphere via the optimal perturbation mechanism. The excitation process involves changes in the southward flow through the Denmark Strait generating salinity anomalies downstream. These results are relevant to other models (e.g. CCSM3 and CESM). (Abstract ID 9735)

Pre-sampling assessments of decadal diversity on deep hard banks and surrounding sediments were continued post-spill under exigent NSF/Rapid and GRI/Stopgap programs. Rubble bank substrates (60-90m) were sampled with 1m box dredges and muddy substrates (150-200m) with 3m epibenthic skimmers. Post-spill sampling has been limited to three cruises, only one matching pre-spill sampling seasons. Diversity and abundance on hard banks decreased from pre-spill measures and across post-spill periods. Assemblage composition shifted dramatically on banks, including near extinction of the previously dominant brachyuran Maldanidae. General expression studies are underway to characterize responses of major lineages to oil-spill stressors. Epibenthic shallow interannual decads in post-spill samples often bear coatings of HC residues, especially on branchiae and appendages used for sediment manipulation. Frequency of lesions increased over post-spill sampling, though patterns were heterogeneous among decad lineages. Lesions appear to involve microbial activity, with possible attenuation of shell defenses by lipotic and chitinoclastic processes. We hypothesize infection pathways linked to weathering of dispersed HCs, enhancing recruitment of shell disease pathogens from natural reserves. Host vulnerability, physiological responses, and disease transmission routes remain our focus. (Abstract ID 11496)

Besides a sea level rise (SLR) trend from 1992 to 2010, the SSHA geographically and temporally varies in this region and is dominated by interannual and interdecadal variability. The SLR in the SGP developed at a reduced rate in the 2000s compared to rates in the 1990s. This rate reduction is accompanied by reduced amplitudes at low frequency SSHA oscillations. General decreasing sea level in the SGP appeared in the 2000s that is mostly associated with variations in the Irminger Basin sea level. Observed decreasing SSH and partially strengthening SGP circulation in the 2000s, however, cannot be explained by changes in the deep ocean convection in the Labrador Sea, even less by variations in the air temperature and the wind patterns in the northern North Atlantic. Rather, a reversal of the SSHA trends over past two decades might be related to the multi-decadal Atlantic meridional overturning circulation (AMOC) variability. (Abstract ID 12372)
UNDERSTANDING HYPOXIC AREA VARIABILITY IN THE NORTHERN GULF OF MEXICO FROM A THREE-DIMENSIONAL COUPLED PHYSICAL BIOGEOCHEMICAL MODEL

A three-dimensional, coupled physical-biogeochemical model (ROMS-Fennel) with an expanded oxygen component has been used to simulate the occurrence and spatial extent of hypoxia in the northern Gulf of Mexico from 1985-2009. Model skill was quantified by comparing simulated oxygen fields with available observations. The results show that the model overestimates bottom DO concentrations by about 1 mg/L, however observed bottom DO variability is successfully captured. Adding this 1 mg/L offset to the commonly used 2 mg/L bound for hypoxia allows the calculation of a simulated hypoxic area that is close to observations. An EOF analysis of monthly hypoxia frequency of the 25-year simulations showed several key spatial patterns. The first-two modes have strong seasonal patterns, explain 70% of the area variability and are highly correlated with Mississippi-Atchafalaya river flow, dissolved inorganic nitrogen concentration as well as wind duration and strength. The effect of wind stress and duration complicates the hypoxic area management strategy. Unlike riverine nutrient loading, which can be reduced through regulation, regional wind variability depends on inherent variations in the global climate system. (Abstract ID 10109)

MODELING RELEASE, TRANSPORT AND INACTIVATION OF FECAL INDICATOR BACTERIA AT AN EMBAYED NON-POINT SOURCE SUBTROPICAL BEACH

A 10-day intensive environmental monitoring effort was conducted at a subtropical beach located in southern Florida, USA (Hobe Beach, Miami) in the summer of 2010. This beach was characterized by frequent occurrences of exceedance of fecal indicator bacteria with the inter-tidal sediment as a major bacterial reservoir. The enterococci levels measured hourly at knee-depth locations demonstrated high spatio-temporal variability both in the water and the sediment. To better understand the role of complex hydrodynamic and morphodynamic processes in affecting microbial water quality, we utilized a nearshore process model (XBeach), coupled with a microbe advection-diffusion equation to represent the release of microbes from sand, entainment through shallow groundwater flow, runoff contribution, and sunlight inactivation. The model successfully reproduced the spatial and temporal trends of enterococci concentration in the beach water including the reproduction of strong diel and tidal signals and the rapid decrease of enterococci levels by one to two orders of magnitude in a 100-m distance offshore from the shoreline. The modeled processes and their sensitivity to environmental forcing by waves and tides will be presented at the conference. (Abstract ID 11643)

MINING EFFICIENCY IN NATURAL FLOWS

In evaluating vertical eddy diffusivities within oceanic stratified layers, a commonly used assumption is that the mixing efficiency G is constant. It is however shown that for stratified shear flows G is dependent on at least two parameters, the gradient Richardson number Ri and the buoyancy Reynolds number Re. Based on direct flux and gradient measurements in stable atmospheric boundary layer and using homogeneous/stationary TKE balance equations, it is shown that in limited parameter ranges the directly evaluated mixing efficiency is nominally similar to that evaluated based on scale balance equations. When Ri and Re are outside these ranges, one or more assumptions used in developing the methodology of flux estimation break down. The results shed light on the wide variability of G noted in previous studies. (Abstract ID 10045)

CLEAN COASTAL WATERS AND PRODUCE BIOFUELS

Nutrient pollution is a growing problem in estuaries and coastal waters throughout the world and innovative strategies are needed to address this environmental problem. As part of a multi-institutional, interdisciplinary effort, we are investigating the culture of wild attached algal communities as a tool for simultaneously removing nutrients from eutrophicated waters while using the accumulated algal biomass for biofuel production. Two research-scale algal flows (25 m long) were established on a tributary of the Chesapeake Bay and operated for 1-2 years to provide reference data on algal production, lipid content and composition, and nutrient concentration and removal. Overall, algal biomass accumulated at moderate to high rates (annual average production = ~20 g m$^{-2}$ day$^{-1}$; peak production [Jun-Oct] = 50 to 60 g m$^{-2}$ day$^{-1}$). Generally, total lipid content of the algae was low and averaged <5% of dry mass for the upper and lower portions of the flows. Our results demonstrate that attached algal flows are highly effective at nutrient removal, thus providing an effective approach for improving water quality. (Abstract ID 9883)

The characteristics of the Probable Maximum Tsunami (PMT) generated by the Probable Maximum Earthquake (PME) at the Makran Subduction Zone (MSZ) where a historic tsunami originated in 1945 was evaluated. The wave run-up/down resulting from the PMT was computed at a typical location in the south central portion of the Arabian Gulf. Seven earthquake scenarios were developed to identify the characteristics of the PME. A separate Seismic Hazard Analysis was conducted to determine the magnitude of the PME. The seven earthquake scenarios were first examined using the European Commission Tsunami model (ECIRC) to determine tsunami scenarios that could impact the site. Later on, Delta3D-FLOW was utilized to compute the wave height near the site. A sensitivity analysis was conducted on the following parameters: bathymetry, tide factor, layout of the site, and modeling techniques. (Abstract ID 10673)

USING A SIMPLE CONVECTION MODEL TO DIAGNOSE GULF OF MEXICO WINTER MIXED LAYER VARIABILITY

Convective overturning is a critical process in the global climate system. The intensity of these processes determines the depth of the Mixed Layer (ML) and ultimately the amount of the water mass formed. Such processes occur in Willingham Basin (WB) in the Gulf of Maine. We present preliminary results on the evolution of the winter ML. Using both observed data and simulations with the Price, Weller and Perles (1986) model (PWP). One of the advantages of PWP allows the user to study the effect of winds and convection separately. The WB atmospheric records exhibit different air-sea exchange scenarios including (1) net surface cooling due to a combination of relatively large air-sea temperature difference and moderate offshore southeastward winds; and (2) surface cooling due to a combination of strong storm-related southeastward winds and a more modest air-sea temperature difference. Preliminary PWP results show a ML deepening due to the cooling observed in the first half of the study period. However, PWP did not reproduce the observed re-stratification during the second half because of the lack of model lateral advection. (Abstract ID 11567)

BIOGEOCHEMICAL CONTROLS OF NITROGEN FIXATION IN THE OXYGEN MINIMUM ZONE OF THE EASTERN SOUTH PACIFIC REGION

Nitrogen fixation was studied between 2007 and 2010 through 15N assimilation in the seasonally active upwelling system off central Chile (35° - 37°S). Intense suboxia causes this site to show important nitrogen sinks through denitrification and anammox near the coast while oceanic waters sustain high levels of primary production fueled by wind driven upwelling of denitrified waters. N2 fixation was an almost permanent feature in the study area. In the euphotic zone, biological nitrogen fixation was detected during the entire study period with rates going from 0 to 5 mmol L$^{-1}$ d$^{-1}$ (0.32 ± 0.17 mmol L$^{-1}$ d$^{-1}$) in 2006 and 0 to 2.93 mmol L$^{-1}$ d$^{-1}$ in 2009 (0.69 ± 0.56 mmol L$^{-1}$ d$^{-1}$). Also, a temporal survey revealed the occurrence of N2 fixation in subsurface suboxic conditions, mainly during non upwelling periods (winter). In order to explore the control factors of this process, the appearance of N2 fixation in the area was analyzed in a wide biogeochemical context, evaluating possible interactions with chlorophyll content and the CN ratio of phytoplankton, as well as the dynamics of other dominant microbial processes in the area such as nitritation. Results suggest that the presence and magnitude of diazotrophic communities is related to the physiological status and composition of the microbial community rather than the extent of N deficiency translated in low N ratios. (Abstract ID 9678)

MIXING EFFICIENCY IN NATURAL FLOWS

In evaluating vertical eddy diffusivities within oceanic stratified layers, a commonly used assumption is that the mixing efficiency G is constant. It is however shown that for stratified shear flows G is dependent on at least two parameters, the gradient Richardson number Ri and the buoyancy Reynolds number Re. Based on direct flux and gradient measurements in stable atmospheric boundary layer and using homogeneous/stationary TKE balance equations, it is shown that in limited parameter ranges the directly evaluated mixing efficiency is nominally similar to that evaluated based on scale balance equations. When Ri and Re are outside these ranges, one or more assumptions used in developing the methodology of flux estimation break down. The results shed light on the wide variability of G noted in previous studies. (Abstract ID 10045)
The annual cycle of phytoplankton growth in many parts of the ocean is dominated by a population explosion in late winter early spring, the so-called spring bloom. High levels of primary production during the spring bloom, and the subsequent sinking of organic material contributes significantly to the carbon flux to the deep ocean. The onset of the spring bloom has been traditionally associated with the shoaling of the mixed layer above a critical depth at the end of winter. However we will argue that the onset of the spring bloom is more likely triggered by the reduction in air-sea heat loss at the end of winter. When net cooling subsides at the end of winter, turbulent mixing in the ocean becomes weak, thereby increasing the residence time of phytoplankton cells in the euphotic layer and allowing a bloom to develop. The necessary change in the air-sea flux generally precedes mixed layer shoaling, and provides a better indicator for the onset of the spring bloom than the mixed layer depth. We will illustrate our results with a combination of theory, numerical simulations, and analysis of remote sensing data. (Abstract ID 11697)

VIRTUAL TOOLS TO AID SCIENTISTS IN DEVELOPING BROADER IMPACT PROJECTS

COSEE Networked Ocean World (COSEE NOW) is dedicated to supporting ocean scientists in successfully communicating the broader impacts (BI) of their research. We have created a suite of new online resources for scientists, which complements and enhances our existing social networking portal (http://coesewnow.net) that brings together researchers and educators from the ocean science community. The “BI Assistant” provides a user interface that guides users through a series of well-defined steps necessary for the construction and implementation of a broader impact statement required in research proposals. The site also features a collection of resources that provides guidance on selecting potential audiences, identifying appropriate collaborators, and developing activities that achieve broader impacts. Case studies highlighting high quality education and public outreach (EPO) projects are included to offer scientists effective strategies for integrating the intellectual merit and broader impacts components of their research. The consolidation of these features into one online environment encourages interdisciplinary sharing of expertise and resources, which consequently enhances the quality of EPO products and promotes dissemination of scientific research. (Abstract ID 11697)

HOW DO OCEAN CIRCULATION AND BASIN GEOMETRY REGULATE THE LARGE-SCALE DISTRIBUTION OF DISSOLVED OXYGEN IN THE GLOBAL OCEAN?

Here we examine fundamental controls on the large-scale oxygen distribution using a suite of integrations with a coupled ocean-atmosphere-sea ice general circulation model, overlain with a simple ocean biogeochemistry parameterization. Basin geometries are idealized, ranging from a pure Aquaplanet (no geometrical constraints) to a more complex, Jurassic-like configuration comprising a small enclosed basin and a large basin. The simulations cover a wide range of ocean circulation regimes, sea-ice covers and climates. Importantly, a configuration with idealized present-day geometry captures the main features of the observed oxygen distribution. The suite of models lead to three key inferences: (i) the expected decrease of the mean O2 concentration with increasing mean temperature (solubility effect) can be significantly disrupted by extensive ice cover and/or weak nutrient utilization, (ii) the presence (and extent) of anoxic waters is poorly correlated with the global mean oxygen concentration but is controlled by large-scale ocean circulation, and (iii) deep anoxia is a possible solution, favored by the presence of 2 basins. Implications of our results for interpreting paleoclimate records and future climate change are discussed. (Abstract ID 11725)

THE EFFECTS OF UV/OD Dopamine RELEASE ON BARNACLE FEEDING BEHAVIOR

The catecholamine dopamine, well known for its role as a neurotransmitter in animals, functions as a herbivore deterrent in the green alga Ulva linza. In addition to its role as a chemical defense, dopamine and its oxidative products have been implicated in reducing the success of competitive algae and larval invertebrates when released by Ulva linza into surrounding waters. Here, we investigated the impacts of Ulva linza dopamine and dopamine on the feeding behavior of the barnacle Chthamalus dalli, a species common in areas that experience large green algal blooms. When exposed to Ulva linza exudates, barnacle cirral extension rates were suppressed relative to seawater alone. Subsequent trials conducted with dopamine, its oxidative products, or seawater confirmed the inhibitory effects of dopamine on barnacle feeding behavior. Our results suggest that high dopamine concentrations associated with Ulva linza blooms can have negative impacts on adult invertebrates including barnacles. (Abstract ID 11360)

COMMUNITY ECOLOGY: HOW OPPOSING DEMOGRAPHIC PROCESSES ARE CONTROLLED BY ONE, AND THE SAME, MOLECULE

Opposing demographic processes are driven by the recognition of sensory cues indicative of suitable habitat and/or prey. In some instances, the signals that induce settlement of, and predation on, a species are one and the same, and so population balance rests on a single compound. We have identified one such molecule produced by barnacles (Balanus glandula)—MULTIFUNCin. At natural concentrations, MULTIFUNCin induced significantly more larvae to settle than did controls. Moreover, MULTIFUNCin triggered predation in five species of barnacle-consuming whelks (Acanthinaulax serpula, Nucella angari, N. osteria, N. lamellosa, N. canaliculata) and sea stars (Pistaster ochraceus). Analysis revealed the nucleotide and amino acid sequences of this protein. The full amino acid sequence of MULTIFUNCin established it as a globular glycoprotein requisite to barnacle cuticle/shell formation. A homologous protein was identified in each of three additional barnacle species (Semibalanus cariosus, Chthamalus stellatus, Amphibalanus amphiibius), indicating conservation of the bioactive compound. When each respective protein was isolated, purified, and imbedded in faux prey, each whelk and seastar species preferentially chose the MULTIFUNCin-laced mimic. MULTIFUNCin recognition thus plays a key role in balancing opposing demographic processes (immigration and death by predation) that determine barnacle population dynamics and structure species assemblages on rocky wave-swept shores. DYNAMICS OF ORGANIC AND INORGANIC CARBON IN A MANGROVE-DOMINATED ESTUARINE SYSTEM (SHARK RIVER, FLORIDA)

We report the results from a Lagrangian SF6 tracer release experiment conducted in Shark River in November 2010, where we examined the source, fate and transport of dissolved carbon in a mangrove-dominated estuary. The main objectives in this experiment were: 1) to determine hydrological parameters, such as net advection, dispersion and residence time of water; 2) to quantify air-water gas exchange; 3) to provide a Lagrangian frame of reference to examine carbon transformation rates. SF6 was released on November 19th 2010 and sampled for 6 consecutive days following the injection. Along with SF6, we made underway measurements of temperature, salinity, dissolved oxygen and partial pressure of CO2 in the tracer-tagged waters and throughout the estuarine salinity gradient. We also collected discrete water samples at different sites along the tracer patch for the analysis of dissolved and particulate organic carbon (DOC, POC), total alkalinity, dissolved inorganic carbon (DIC), DOC optical properties, POC biomarkers and δ13C of DIC, DOC and POC. The results suggest that the Shark River and surrounding intertidal sediments are active sites for mangrove-derived carbon mineralization. (Abstract ID 12299)

GLORYS 1/4° GLOBAL OCEAN REANALYSES AND SIMULATIONS OF THE PERIOD 1992-PRESENT

We present here the French GLORYS (Global Ocean ReanalYses and Simulations) project, in which several global ocean reanalyses have been carried out. GLORYS reanalysis system describes the evolution of the ocean and sea-ice states and is based on Mercator Ocean operational 1/4° global eddy-permitting ocean analysis and forecasting system (http://bulletin.mercator-ocean.fr/html/products/ps3v3/ps3v3_data_en.jsp). The NEMO ocean model
is forced by ERA-Interim atmospheric parameters including satellite-based fluxes corrections. The data assimilation method is based on a reduced order Kalman filter (SEEK formulation) in conjunction with a bias correction scheme for temperature and salinity. Assimilated data are delayed time SST, along track SLA and in situ T,S profile data. Two reanalyses and one reference simulation with no data assimilation have been produced, validated and are distributed. The first stream covers the “auger era” (2002-2008) and was produced end 2009. The second stream covers the “altimetric era” (1992-2009). We present in this study the skill of GLORYS reanalyses and give an overview of results obtained in a wide range of areas such as climate, meso scale processes, mixed layer processes, sea ice... LONG-TERM MONITORING OF ERUPTIONS AND GAS HYDRATE DYNAMICS AT THE HÅKON MOSBY MUD VOLCANO, BARENTS SEA SLOPE

Located at 1250 m water depth on the Barents Sea slope, the Håkon Mosby mud volcano was the focus of a long-term observation within the framework of the ESONET demonstration mission LOOMÉ. Previous investigations had indicated persistent high rates of seepage as well as abundant gas hydrates and led to the installation of an un-cabled modular seafloor observatory. Temperature at the seabed and in the sediment along with pressure, temperature, current speed and direction, pH, and oxygen in the bottom water were recorded from July 2009 until September 2010. These time series document several eruptive events associated with explosive uplift of the seafloor, sharp drops in bottom water pH and oxygen, and increased turbidity and sediment temperatures, and rapid mud expulsion. Based on the timeline of these events, we propose a conceptual model that explains how episodic seepage of warm fluids controls gas hydrate dynamics and triggers eruptions of the Håkon Mosby mud volcano. THE SPECTRAL SLOPE COEFFICIENT OF CDOM (S_CO) AS A TRACER OF TERRIGENOUS DOC IN RIVER-INFLUENCED OCEAN MARGINS

Rivers exert an important control on carbon dynamics and CO2 fluxes in ocean margins by improving ocean margin carbon budgets. Here, we observed a strong disturbance caused by the passage of tropical storm Kiko through the study area in early October, with effects cascading from the physical environment up to top predators. Surface temperature mean and patchiness decreased with an increase in macrozooplankton biomass, although changes in dietary composition were slight. Hypotheses are presented to explain how Kiko induced these bottom-up ecosystem changes. (Abstract ID 10008)

DO THE SILICIFIED WALLS OF DIATOMS CONFER PROTECTION AGAINST COPEPOD GRAZING?

Many groups of marine protists (algae and protozoa) are “armored” with thickened cell walls, coatings of scales, hard “cases” (tests, loricas), or latticework “skeletons”. One of the inferred evolutionary functions of these mineral deposits is to deter grazing. However, to date there are no direct measurements of grazing rates on protists as a function of their mineral content. With the recent development of silica stains we directly test the relationship between the per cell minerals quota of 2 diatoms species (Thalassiosira sp.) and the ingestion rates of copepods. Mineral load were determined chemically (chemical digestion), visually (confocal microscope) and photometrically (flow cytometry). Using well controlled algal rearing techniques, we grew phytoplankton cells with a 3 fold difference in silification. Our results show that for small cells (T. pseudonana) the degree of silification showed no effect on grazing rates by Acartia tonsa. For larger cells (T. weissflogii), we found a significant effect of silica but only at high cell concentrations. These results support the hypothesis that silification in some cases does confer protection against mesozooplankton grazing rates. (Abstract ID 11038)

GULF OF MAINE AND THE WORLD OCEAN REU: ATTRACTING AND RETAINING MINORITY STUDENTS IN OCEAN SCIENCES

Bigelow Laboratory for Ocean Sciences, site of the Gulf of Maine and the World Ocean REU, provides undergraduates the opportunity to develop skills conducting independent scientific research in lower trophic level oceanography using state-of-the-art methods and research technologies. Our goal is to increase the number of underrepresented minority students pursuing graduate degrees in ocean science, with an emphasis on engaging Native Americans. We work directly with minority-serving institutions and organizations to meet this goal. To date, twenty-four students have participated in the REU, with over 40% minority participation during the last two years. Nine students have received funding to present their work at international science meetings. In August 2011, an external evaluator was hired to assess our first three years as an REU site; here we present these evaluation results, focusing on the short and long-term impacts of the program on minority participants and their post-program academic and career paths. Effective strategies for recruiting and mentoring underrepresented minority students, as well as challenges faced in meeting our recruitment goals and lessons learned, will also be discussed. (Abstract ID 9764)

SENSOR EVALUATION OF THE HYDROC-CO2 FROM VARIOUS FIELD TESTS

Driven by the need for small, versatile, autonomous and reliable sensors for the partial pressure of carbon dioxide (pCO2), the development of the HydroC-CO2 was initiated in 2007. The HydroC is an in situ or flow through instrument that determines the CO2 concentration optically by means of non-dispersive IR-spectrometry (NDIR) within a membrane-equilibrated gas stream. Within the last years various successful laboratory and referenced field measurements were conducted. The track record comprises deployments for timescales extending from hours to months in rivers, coastal waters and the open ocean. The instruments were installed on or integrated into diverse platforms ranging from stationary buoys over research vessels to modern moving platforms such as AUVs or even profiling floats. Data was collected in surface waters during underway measurements and within the water column during profiling CTD casts down to 2000 m. This contribution aims at providing a comprehensive performance assessment of the HydroC-CO2 instrument. Considering its versatility, potentials and limits are discussed as well as areas of future optimizations identified. (Abstract ID 17178)

ELEVATED TEMPERATURE/PCO2 SYNERGISTIC EFFECTS ON TROPICAL MARINE MACROALGAE AND SEAGRASSES

Ocean pCO2 is expected to approach ~1,000 ppm and temperatures increase by ~4°C by 2100. We present data on the physiological responses of tropical calcifying and non-calcifying macroalgae and seagrasses with important roles in reef, lagoon, estuarine and open-water systems to the interactive effects of elevated pCO2 and temperature. Our ongoing research is evaluating metabolic effects of and growth of elevated pCO2 across seasons using a well-controlled mesocosm facility (16 500L tanks) with a web-controlled monitoring system that injects CO2 to maintain pH (±0.03; verified CO2SYS & measuring pCO2aq). In May/August 2011, we evaluated elevated temperature (28/34°C) and pCO2 (PH 7.69) to controls (24/30°C pH 8.07) and photosynthesis/photoinhibition irradiance parameters (Pmax, Ic, Ik, and α) determined. At high pCO2 and ambient temperature, Pmax was elevated in all species. An increase in production was also observed in Halimeda at high pCO2 x high temperature in spring; however, high pCO2 x high temperature in summer lowered production. Our data indicate tropical macroalgae and seagrasses adjust to elevated pCO2 and temperature through temperature controls on respiration and photosynthesis; with threshold responses observed approaching thermal limits. A HIGH-FREQUENCY, BROADBAND ACOUSTIC BACKSCATTERING SYSTEM, FOR IMAGING, CLASSIFICATION, AND QUANTIFICATION OF WATER-COLUMN SCATTERERS FROM AUTONOMOUS VEHICLES

For decades, significant research effort has been directed at using high-frequency acoustic scattering techniques to remotely investigate marine organisms and small-scale fluid processes. Acoustic scattering techniques provide a rapid, high-resolution, synoptic, remote-sensing tool that complements more traditional sampling strategies such as nets and optics. Autonomous vehicles offer advantages in persistence and spatial coverage, and are expected to play a critical role in ocean observing systems. Emerging broadband scattering techniques result in increased range-resolution and spectral coverage, improving imaging, classification and quantification capabilities. A low-power, short-range, compact, autonomous, broadband (120–1200 kHz) backscattering system appropriate for mounting on autonomous platforms has been developed. After successful tests in an estuary to image stratified turbulence, this system was recently mounted on a REMUS-100 AUV for studies of zooplankton and fish ecology. Test deployments off of Stellwagen Bank demonstrated the system is most suitable for measuring strong scattering at short ranges, and that the system was able to perform multi-mode operations of varying depths, spatial patterns, and transducer orientations, complementing data collected simultaneously with ship-board acoustic systems and traditional optical and net systems. THE RATIONALE FOR A SUSTAINED DEEP OCEAN OBSERVING SYSTEM: OCEAN AND CLIMATE PHYSICS

The deep ocean emerges as a crucial player of ocean and climate variability on longer time scales. The ability to understand and quantify physical processes affecting its variability sets stringent budget and drift constraints on ocean state estimates. They are also crucial to improve climate models, a prerequisite for decadal to century-scale global and regional climate projections. Finally, well-constrained global physical circulation fields are crucial for driving coupled biogeochemical and ecology models, for which the source of uncertainties in the physical state ought to be minimized in any possible way. PAH BIOACCUMULATION IN MARINE BIOFOULING INVERTEBRATES IN THE NORTHERN GULF OF MEXICO

The northern Gulf of Mexico continental shelf is among the most ecologically productive regions in North America. However, it is also rich in oil deposits resulting in continuous natural seepage of oil components into the ecosystem. The natural release of oil is potentially enhanced by the approximately 6,000 petroleum platforms present in the gulf. The net result is an ecosystem highly exposed to petroleum polyaromatic hydrocarbons (PAHs). Sesel marine invertebrates have routinely been utilized to examine oil exposure and PAH accumulation (e.g. NOAA Mussel Watch program), but few studies have examined the extent of PAH bioaccumulation in biofouling organisms living in such highly exposed regions. This study examined PAH bioaccumulation in two common biofouling invertebrates: the oyster, Ostrea equestris, and the coral, Turbinaria crocea, located on artificial structures throughout the northern Gulf of Mexico. For both organisms, 52 individual PAHs, including alkylated and non-alkylated forms extracted from whole animal samples, were measured by GC/MS and normalized to lipid content. For oysters, PAH bioaccumulation will be subsequently compared to biomarker analysis of PAH exposure and effects in digestive tissue. (Abstract ID 11570)

CLIMATE CHANGE INFORMATION NEEDS IDENTIFIED BY CALIFORNIA COASTAL MANAGERS

Decision-makers in California's coastal areas generally recognize that climate change will impact their communities and coastline and are at different stages in developing and/or implementing climate change adaptation plans. Many communities understand the need to include the best available science in their planning and decision-making. We conducted a statewide survey, in partnership with 15 California local, regional and state-based organizations, aimed at coastal professionals, to understand the scientific information, data, training, and technical assistance needs as well as barriers coastal communities face in planning for climate change impacts. This survey builds on a survey conducted in 2005 and provides the first-of-its-kind longitudinal analysis of climate change adaptation planning for the state of California. Often there is a disconnect between what information decision-makers need to move forward in adaptation planning, compared to what scientists believe decision-makers need. Effective communication of scientific results requires first understanding the needs of the target audience. The results of the 2011 survey and the comparison with the earlier one give insights into what decision-makers identify as their science needs and the manner in which they can utilize this information, allowing us to find more useful ways of translating the science for these end-users. VORTICITY BALANCE IN DRAKE PASSAGE

As part of the CDrake experiment, an array of current meter-pressure sensor-inverted echo sounders deployed at 46 km spacing in the Polar Frontal zone in Drake Passage has provided three years of daily near-bottom current, bottom pressure, and round trip vertical acoustic travel time between sea floor and sea surface with spatial resolution sufficient to capture mesoscale eddies. Using empirical relationships determined by historical hydrography, objective maps of travel time data can be converted to vertical profiles of baroclinic currents. Daily geostrophic currents and bottom pressure thus enable us to estimate the terms of the geostrophic momentum and vorticity balances. Relative vorticity advection is an order of magnitude larger than planetary vorticity advection. (Abstract ID 10698)
**OCEAN OBSERVING SYSTEM**

The “Framework for Ocean Observing” is fully described at [http://www.oceanobs09.net](http://www.oceanobs09.net). The Framework is being utilized as a tool to reform and further develop the Global Ocean Observing System (GOOS). It provides a system-level view of best practices for setting requirements, coordinating observation networks, and delivering information products for sustained global ocean observing to address scientific and societal issues. The Framework brings together a suite of ideas to re-energize development of global ocean observing infrastructure. It embraces a key theme of OceanObs’09 to broaden sustained global ocean observing across ocean science disciplines. It suggests appeal to international conventions beyond the United Nations Framework Convention on Climate Change. The concept of communication across the system in terms of “Essential Ocean Variables,” is modeled after the open ocean. Data was extracted from vessel mounted ADCPs during survey cruises in a 10 by 10 degree area covering the North Atlantic Oxygen Minimum Zone (OMZ). Shear spectral levels are a proxy for turbulent diapycnal diffusivity which in turn allowed calculation of diapycnal gas transports. The used 75 kHz ADCPs, after corrections for underway biases, resolve the occurring range of internal wave shear from background levels up to peak levels. To relate finescale shear to turbulent mixing, the existing finescale parameterization was checked against own microstructure observations showing general agreement. Nonetheless, here we suggest a simpler empirical parameterization, more appropriate for ship cruise needs. The analysis of data from below the sharp thermocline down to 500m depth showed horizontal patterns of topographically enhanced internal wave activity, and revealed diapycnal oxygen transport as one key supply for the OMZ. Given internal wave breaking as dominant source of turbulence and given detectable concentration gradients, the method should be adaptable at similar ADCP frequencies to other regions and substances. (Abstract ID 11321)

**UNDERWAY ACOUSTIC SURVEY OF INTERNAL WAVE SHEAR; AND ITS USE TO ESTIMATE DIAPYCNAL MIXING AND TRANSPORTS IN THE INTERIOR OCEAN**

We report on continuous underway acoustic measurements of internal wave shear in the open ocean. Data was extracted from vessel mounted ADCPs during survey cruises in a 10 by 10 degree area covering the North Atlantic Oxygen Minimum Zone (OMZ). Shear spectral levels served as proxy for turbulent diapycnal diffusivity which in turn allowed calculation of diapycnal gas transports. The used 75 kHz ADCPs, after corrections for underway biases, resolve the occurring range of internal wave shear from background levels up to peak levels. To relate finescale shear to turbulent mixing, the existing finescale parameterization was checked against own microstructure observations showing general agreement. Nonetheless, here we suggest a simpler empirical parameterization, more appropriate for ship cruise needs. The analysis of data from below the sharp thermocline down to 500m depth showed horizontal patterns of topographically enhanced internal wave activity, and revealed diapycnal oxygen transport as one key supply for the OMZ. Given internal wave breaking as dominant source of turbulence and given detectable concentration gradients, the method should be adaptable at similar ADCP frequencies to other regions and substances. **MODELING OF DALL’S PORPOISE HABITAT PREFERENCES: USING ACOUSTIC OBSERVATIONS**

This investigation is focused on the nearshore wave field transformations by combining spectral wave simulations, SWAN, and wave field measurements (provided by BSH) for a broad variety of different meteorological and oceanographic conditions. The default SWAN and a modified version of SWAN, Veermany et al. (2010), which uses the variational approach in order to assimilate measured wave spectra and to apply them as boundary conditions, are applied for the North Sea. The outputs of the two models are validated at different depths and the spectra of the models are intercompared, in order to identify and quantify the wave energy dissipation. In this frame, the outputs of SWAN, in littoral zone, are compared with measurements of the velocity of wave crests and of the probability of wave breaking derived from Doppler X-band radar measurements (data provided by HZG), Flammarion (2010). The comparison proves significant correlation between measurements and models, but also their combination permits the determination of the contribution of each wave energy dissipation component (breaking and bottom friction). (Abstract ID 10586)

**MODELLING OF DALL’S PORPOISE HABITAT PREFERENCES: USING ACOUSTIC DETECTIONS TO IMPROVE ECOLOGICAL UNDERSTANDING**

A fundamental step in modeling species ecology is the collection of accurate population size and distribution data. This is especially challenging for less conspicuous or deep-diving cetaceans. Dall’s porpoise, a common, vocally-active cetacean found in cool waters of the North Pacific, is nearly impossible to sight in rough seas due to its small body and group
EXPLORING UNDERWATER FEATURES AT BIRKA, A VIKING HARBOR, USING A MULTIRESOLUTION ACOUSTIC ARRAY

Ocean exploration can involve travel to the ends of the Earth, but there is much to learn in our own back yard. We recently conducted an ultra high resolution multibeam survey using a new EM2040 multibeam survey system in Lake Malaren off the Viking trading port of Birka which was active in the 8th through 10th century. Those connections were cut off as post-glacial rebound caused the ocean to retreat. This World Heritage Site has been studied for over 200 years and is less than 10 km west of Stockholm. Divers have found an offshore palisade of poles, and the multibeam exposed poles are in areas of minimal recent sediment accumulation, and this observation helps to plan a strategy to search for Viking materials in sedimented areas. Our results here are consistent with those from the Hudson River where high resolution multibeam data near our own back yard. We recently conducted an ultra high resolution multibeam using a new

EXPLORING UNDERWATER FEATURES AT BIRKA, A VIKING HARBOR, USING A ULTRA HIGH RESOLUTION MULTIBEAM ECOSOUNDER

Ocean exploration can involve travel to the ends of the Earth, but there is much to learn in our own back yard. We recently conducted an ultra high resolution multibeam survey using a new EM2040 multibeam survey system in Lake Malaren off the Viking trading port of Birka which was active in the 8th through 10th century. At the time Birka was a coastal community and connected to the Baltic, but those connections were cut off as post-glacial rebound caused the ocean to retreat. This World Heritage Site has been studied for over 200 years and is less than 10 km west of Stockholm. Divers have found an offshore palisade of poles, and the multibeam exposed poles are in areas of minimal recent sediment accumulation, and this observation helps to plan a strategy to search for Viking materials in sedimented areas. Our results here are consistent with those from the Hudson River where high resolution multibeam data near an urban center revealed hundreds of shipwrecks. (Abstract ID 12721)

FLORIDA KEYS BIOGEOCHEMICAL CYCLE RESEARCH AND UNDERSTANDING, AND THE ROLE OF MIXED LAYER DYNAMICS

In the first half of 2009, anomalous cooling of sea surface temperatures (SSTs) in the equatorial North Atlantic (ENA; 2N-12N) triggered a strong Atlantic meridional mode event. This study uses in situ and satellite observations to examine the mechanisms responsible for the anomalous cooling in the ENA during boreal winter and spring of 2009. It is found that the cooling was initiated by stronger than normal trade winds during Jan-Feb 2009 associated with an anomalously strong SST gradient. These results emphasize the importance of mixed layer dynamics in the evolution of the meridional mode event of 2009 and the potential for positive coupled feedbacks between wind-induced upwelling and SST in the equatorial North Atlantic. (Abstract ID 9755)

PALEOCEANOGRAPHY AND BIOGEOCHEMICAL CYCLE RESEARCH

Stable isotope analysis is gaining momentum as a tool for investigating the trophic ecology of gelatinous species and to complement existing dietary studies. Strangford Lough (Northern Ireland, UK) is a large, semi-enclosed embayment that is characterised by an elevated diversity of gelatinous zooplankton; as such, it represents an excellent location to examine the functional role of these taxa. Here we report isotopic data from six abundant species of gelatinous zooplankton (ctenophora and cnidaria). To understand the role of these taxa in coastal marine waters, we examine δ13C and δ15N stable isotope ratios and use mixing models to examine (1) intra-guild predation amongst gelata, (2) allometric shifts in diet, and (3) how temporal shifts in community structure alter the combined impact of gelatinous zooplankton on temperate coastal food webs. (Abstract ID 11069)

ESTIMATING THE ISOTOPIC DISTRIBUTION OF DISSOLVED ORGANIC MATTER

Carbon isotopes are one of the most effective tools we have to understand the sources, composition and cycling timescales of dissolved organic matter (DOM) in the ocean. The past decade has seen an evolution of isotope measurements from bulk techniques to analyses targeted at specific fractions and molecular components of DOM. We have expanded this approach by coupling ultraviolet oxidation analysis of whole seawater with inverse numerical techniques to estimate the distribution of carbon isotopes within DOM. The isotopic distributions from a simple depth profile (50, 500, and 2000 meters) at Station ALOHA, off Hawaii, are compared to the standard two-component model of labile and recalcitrant DOM cycling. Our analyses suggest that there are at least four distinct components of DOM occurring throughout the water column, and that the carbon flux through deep ocean DOM could be an order of magnitude larger than current models predict. These results emphasize the importance of mixed layer dynamics in the evolution of the meridional mode event of 2009 and the potential for positive coupled feedbacks between wind-induced upwelling and SST in the equatorial North Atlantic. (Abstract ID 9755)
As part of a study looking at lateral dispersion processes on the continental shelf, we present analysis of hydrodynamic data from a high density array of velocity, temperature, and salinity and meteorological conditions over the middle and outer continental shelf and how the larger scale dynamics drive local scale motions and stratification. We speculate that the regional shelf scale meteorology and hydrodynamics are inherently linked to the local scale variability and lateral dispersion observed on the inner shelf. (Abstract ID 11536)

Although Euterina acutifrons is identified as a monotypic species, the existence of species complex has been suspected because of its wide distribution and the geographical variations of male dimorphism. While the karyological study is one of the approaches to reveal the existence of species complex in copepods, it is difficult to perform an accurate karyotyping under light microscopy observation because of small size of copepod chromosomes. In order to observe the copepod chromosomes in higher resolution, we investigated the application of rotary shadowing process for SEM observation. Copepod chromosome for SEM observation. Relative length, arm ratio, and centromic index were determined on 2n = 20 chromosomes for the four regional populations. The karyotype formula of E. acutifrons showed chromosomal polymorphism among different populations, implying E. acutifrons species complex may exist. (Abstract ID 10856)

Quantifying the net flux of organic carbon and dissolved nutrients from the terrestrial to the coastal environment via a tidally varying estuary presents particular problems when using wet chemical analyses and conventional hydrological discharge estimates. We used a side looking velocimeter attached to a pylon, in conjunction with a range of high frequency bio-optical instruments to infer the fluxes of dissolved organic and nitrate from the periurban Logan estuary in Queensland, Australia. We discuss how the estimated fluxes vary, the size of the relative errors and their dependence on the number of observations, and the changes in estimated flux due to variations in the freshwater discharge. The estuarine output fluxes are compared to upstream inputs from known point sources. In addition, we made short term deployments of the same suite of bio-optical instruments, an ADP velocimeter, and a continuous PC02 device at several other sites within the estuary. At several sites the strong coupling between water column PC02 and the water velocity is attributed to intermittent resuspension of a heterotrophic sediment layer. (Abstract ID 10761)

The shelf-slope system in the southeastern Beaufort Sea is characterized by extreme physical and biochemical gradients and represents an ideal region to investigate ecosystem processes in the rapidly changing Arctic Ocean. Here, we explore the dynamics of vertical POC/PON fluxes across this region using a high-resolution dataset collected during the Malina campaign in late summer 2009. Vertical fluxes were derived from the size-distribution of large aggregates (0.1-4 mm) as recorded at 154 occasions with an Underwater Vision Profiler and following a calibration against sediment trap data. Spatial interpolation of vertical flux profiles across the 3D shelf-basin environment revealed a patchy distribution associated primarily with: 1) a widespread subsurface chlorophyll maximum, 2) the resuspension and transport of shelf sediment, 3) the turbid Mackenzie River plume. Statistical analyses between the magnitude of POC/PON fluxes and ancillary environmental conditions (sea ice, runoff, hydrography, depth), biological factors (phytoplankton dynamics, bacterial production, zooplankton biomass) and qualitative parameters (lipid tracers, stable isotopes) were conducted to better understand the complex interplay of variables that governs the vertical export of POC and PON across the Beaufort shelf-basin system. (Abstract ID 11613)

understanding of mixing parameters remains very weak. In the quasi-absence of direct observations, most estimates rely on high resolution model diagnostics and indirect inferences of mixing from observations. Here we use the MITgcm/ECCO state estimation technology to make inverse estimates of ocean mixing. Three types of mixing coefficients (vertical, isopycnal and eddy) were therefore added to the list of adjustable parameters in ECCO. Along with forcing and initial condition adjustments, the adjusted mixing proves very efficient in improving the state estimate and the fit to observations. In this presentation, we first demonstrate this result, and discuss the relative importance of the different mixing parameters in our experiments. We then assess the inverted mixing maps and put them in the perspective of previous estimates and theoretical work. (Abstract ID 12476)

OBIS-USA: A NATION BIOLOGICAL DATA RESOURCE FOR ANALYSIS AND MODELING

The Ocean Biogeographic Information System – USA (OBIS-USA) is a national marine biogeographic data asset that contains biological occurrence data that are taxonomically spatially and temporally resolved. Linked to the Intergovernmental Oceanographic Data and Information Exchange, international OBIS, (iOBIS), it is a model for Federal data systems to manage data throughout its life-cycle. The database contains over 7 million records including more than 84,000 species from US marine waters. The data conform to an international data schema (Darwin Core) that renders them interoperable both internally and with other resources. Each individual dataset within OBIS-USA is documented using the FGDC (Federal Geographic Data Committee) metadata content standard, and essential aspects of ISO and CF (Climate & Forecast) metadata conventions are also addressed. This presentation briefly summarizes the OBIS-USA data process; describes OBIS-USA goals for data quality; suitability for use, richness of detail and extensibility; and describes OBIS-USA strategies and technologies for data analysis and integration with in situ data and applications such as modeling and forecasting. INTERNAL WAVE ENERGY AND TURBULENT BREAKDOWN OF LEE WAVES GENERATED OFFSHORE COSTA RICA THROUGH SEISMIC OCEANOGRAPHY

The acoustic imaging and data analysis techniques currently employed in seismic oceanography are rapidly becoming more complex; beyond first-order observation of oceanic structures it is possible to extract quantifiable information about internal wave energies and turbulent dissipation rates. We use two consecutive acquisition surveys at the same location, varying in shot spacing and time, to image a standing lee wave pattern created by flow over rough isopycnal displacements. Through a horizontal wavenumber analysis of tracked continuous reflections in the seismic image we estimate internal wave energy and its associated turbulent dissipation rates across the seismic image. We find increased internal wave energy and associated non-local turbulent dissipation around the lee wave as compared with background ocean levels at two points in the tidal cycle. NANOSMIS IMAGING OF N. C. AND P. ASSIMILATION IN FIELD POPULATIONS OF DIATOM-RICHELIA SYMBIOSES AND TRICHODESMIUM SSP FROM THE WTN

During two separate field expeditions to the western tropical North Atlantic (WTNA), the heterocystous cyanobiont, Richelia intracellularis were observed in association with diatoms Hemiaulus and Rhizosolenia. High cell densities (10^6-10^8) estimated by qPCR were observed during the summer 2010 cruise, and were regularly observed at intermediate to higher salinities (>32-35 PSU). During fall 2011, Hemiaulus-Richelia symbioses co-occurred with the filamentous non-heterocystous cyanobacteria Trichodesmium spp. at modest cell densities (100-300 cells L^-1). NanoSIMS imaging of individual Hemiaulus-Richelia symbioses show high N-enrichment (atm% 0.4413-1.492) than measured on the bulk particles (atm% 0.3708-0.4368) during summer 2010, suggesting an underestimation of N2 fixation by a bulk approach. The C-enrichment, however, showed an opposite trend. Surface cell concentrates containing Hemiaulus-Richelia and Trichodesmium show similar 33P uptake (43-45 nM h^-1) compared to bulk measures (50-60 nM h^-1). NanoSIMS imaging and cell specific 15N, 13C, and 33P assimilation in individual diatom symbioses and Trichodesmium will be compared to the bulk analysis. (Abstract ID 10882)

USING SURFACE PRESSURE DATA TO IMPROVE TROPICAL CYCLONE SAR WIND RETRIEVALS

We seek optimal surface wind vector fields and sea-level pressure (SLP) patterns derived from SAR images of the sea-surface underneath tropical cyclones. Geophysical model functions that link the surface wind vector and the SAR radar backscatter are currently poorly characterized in the very high wind conditions that are present in TCs. In situ calibration and validation wind data are rare in much of the world’s oceans and often (GPS-drop sondes and airborne stepped-frequency microwave radiometers aside) suspect. However, surface pressure observations are less susceptible to measurement errors in the harsh TC environment. We use North Atlantic and images acquired during the CNR-sponsored ITOP experiment in the West Pacific (2010) and drop sonde data to demonstrate the technique. We show that re-derived surface wind field from the SLP pattern are a significant improvement on the directly retrieved input wind vector fields. This is because the SLP is a scene-wide integration of the wind field that optimally spreads the inherent error across the whole scene; the lowest-quality wind vectors tend to be modified more than the highest quality wind vectors. LEARNING FROM SCIENTISTS AT SEA: THE GREAT BELT RESEARCH CRUISE AS AN INTERDISCIPLINARY TEACHING TOOL

In early 2011, scientists from seven institutions spent five weeks in the South Atlantic examining phytoplankton in the Great Southern Cocolithophore Belt, an 88 million km² region in the Southern Ocean with high concentrations of cocolithophores. I joined the NSF-funded “Great Belt” research cruise as an Educator at Sea to connect students and the public with the cruise, focusing on engaging inland and underrepresented minority students. Goals of the project were to increase ocean literacy through exposure to oceanographic fieldwork and provide opportunities for scientists to share their research with new audiences. More than 550 students participated in activities during the expedition, learning about the overall goals of the research, sample collection methods, data processing, hypothesis testing, ecosystems, ocean science careers, life at sea, and engaging in hands-on investigations in their classrooms. Cruise data, daily updates, photos and interviews were shared through a website, blog, photos and direct interactions through email and Skype. This presentation describes the project activities and accomplishments, including ways to evaluate and improve ship-to-school projects in the future. (Abstract ID 10591)

BIOMAGNIFICATION OF MERCURY AND ARSENIC IN THE EASTERN CHUKCHI SEA

Concentrations of Hg, As and stable nitrogen isotopes were determined for eight lower trophic level organisms from the eastern Chukchi Sea (mixed zooplankton, Ampeclocula macrochropha, Astarte borealis, Baccinum sp., Neptuna hros, Chionocytes opilio, Boreogadus saida and PleisicusKeysry). Such information is needed to determine the present-day status for species that may show increased bioaccumulation and biomagnification in a changing climate. Average concentrations of total Hg (THg) increased with trophic level from 7.8 ng/g (dry weight) in zooplankton to 456 ng/g in P. Keysry. As much as 20-fold ranges in THg values were obtained for a given species due to various environmental parameters. Despite this variation, the percent monomethylmercury increased by a relative standard error of <1% for each species. Biomagnification of THg was found to follow the equation log[THg] = 0.19[(δ15N] - 6.63 (r²=0.80, p<0.05). Like Hg, As concentrations varied within and among species with a range for all species of 1.6-154 µg/g (dry weight). Biomagnification of As also was observed with a biomagnification power of 0.26 following the equation log[As] = 0.26[(δ15N] - 2.07 (r²=0.82, p<0.05). (Abstract ID 11878)

AN OVERVIEW OF THE NOAA INTEGRATED APPROACH TO OCEAN AND COASTAL MAPPING

This paper provides an overview of the NOAA Integrated Mapping Program (IOCM) and presents examples of how interagency and internal Ocean and Coastal Mapping (OCM) efforts are working to address the complex and pressing issues identified in the 2010 National Ocean Policy (NOP) and recent legislation, the Ocean and Coastal Mapping Integration Act of 2009. The Interagency Working Group on Ocean and Coastal Mapping (IWG-OCM) continues to address accessibility to and discovery of OCM data, and has recently developed a prototype OCM Inventory, which is discussed in the draft NOP Strategic Action Plan. We will discuss how NOAA is streamlining operations, minimizing redundancies, improving efficiencies, and developing common data standards. The emerging NOAA Rolling Deck to Repository (NOAA R2R) effort, based on the UNOLS R2R, illustrates how OCM data and products are managed and made publicly available to users. (Abstract ID 12209)

BIOGEOGRAPHY AND THE MANAGEMENT OF LARGESCALE ECOSYSTEMS (LMEs)

Large Marine Ecosystems (LMEs), the opportunity for a network of LMEs spanning space, time and stakeholder scales is becoming a reality. These networks define specific components of interest to support the implementation of NOAA's Driver-Pressure-State-Impact Response framework (DPSIR) decision framework and the cyberinfrastructure technologies to ensure data interoperability and reuse. Until now, what was lacking was a process to bring together existing knowledge networks to identify, review, and synthesize the best assessment and management practices among the community of LME practitioners facilitating exchange of lessons learned. The scope of the network includes key stakeholders in four areas: scientists and data providers, agencies, national communities of practice, and decision makers/policy developers. Key to developing network activities is semantic rich use case development using expertise in semantic web methodologies, especially related to diverse vocabulary needs across the stakeholder areas. PARAMETERIZATION OF SUBMESOSCALE AND LANGMUIR-SCALE PROCESSES AND INTERACTIONS

Recent work has shown that small-scale processes, even on the scale of 1m to 10km, have significant systematic impact on the climate. Restratiﬁcation by submesoscale mixed layer eddies has been parameterized in many of the models for the upcoming IPCC ﬁfth assessment. Additional mixing due to surface waves driving boundary layer turbulence (Langmuir turbulence) has also been tested. The impacts of parameterizing these submesoscale and Langmuir-scale phenomena in climate models will be quantified. Remaining issues, especially parameterization of the coupling between Langmuir-scale and submesoscale processes in Large Eddy Simulations of the boundary layer and the implications for parameterization, will be discussed. DIVERSITY AND COMMUNITY STRUCTURE OF CORAL-ASSOCIATED BACTERIA AND ARCHAEA: INTERSPECIFIC, VERTICAL AND SPATIAL VARIATION

Bacterial and archaeal communities associated with the surface mucus layer of three Caribbean reef-building corals (Montastraea annularis, Porites astreoides and Siderastrea siderea) were investigated from two depths (5 and 15m) and at varying spatial scales off Curaçao. Three colonies were sampled per species from three different reef patches at three distinct reef locations (n=162). Water column and sediment samples were taken as reference sites. Prokaryotic community structure was determined using terminal restriction fragment length polymorphism (T-RFLP) and automated ribosomal intergenic spacer analysis (ARISA). T-RFLP and ARISA profiles were correlated to, respectively, 165 and 166-IT5 rRNA clone libraries to identify microbial taxa involved in community shifts. Our findings suggest that mucus-associated prokaryotic communities vary substantially with host species and depth, but also at a small spatial scale between neighboring reef patches. Understanding the distribution of bacterial and archaeal communities thriving on coral mucus is part of a broader effort to link the dynamics in the chemical composition of the mucus layer, its secretion and release to related changes in the structure, abundance and function of its associated microbial communities. CORAL GROWTH ANOMALIES AT WAIOPAE, HAWAII

Coral health throughout the world is declining due to stressors like coral diseases, one of which is called coral growth anomaly (GA). GAs affect the physiology of coral, causing a reduction in coral growth, and are generally associated with heavy metal and pathogenic bacterial and archaeal communities. GAs are thought to be driven by environmental factors such as changes in water temperature, pH, salinity, and nutrient levels. To better understand the causes of GAs, it is important to study the factors that control their occurrence and severity. In this study, we investigated the factors that control GAs in a coral reef located in the Waiopae, Hawaii, USA. We monitored the occurrence of GAs over a period of two years and analyzed the environmental factors that contributed to their occurrence. The results showed that the occurrence of GAs is influenced by changes in water temperature, pH, and nutrient levels. These results suggest that changes in environmental factors can lead to the occurrence of GAs, and that efforts to mitigate these factors could help reduce the occurrence of GAs in coral reefs. HIGH-RESOLUTION OBSERVATIONS OF WINTERTIME DEEP CONVECTION IN THE LABRADOR SEA

Seagliders are used to make high resolution observations during wintertime deep convection in the Labrador Sea. Using novel methodology to derive vertical velocities from the glider CTD measurements, we test theoretical scalings for vertical velocities in narrow convecting plumes vs. the wind-driven mixed layers. While convecting plumes had vertically well-mixed and active mixing temperatures, salinities and densities, the horizontal density variations between sectors.
plumes exceeded 0.02 kg m⁻². This locally available buoyancy has important ramifications for restratification processes after deep convection. (Abstract ID 12175)

NEW OOI PLATFORMS FOR LONG-TERM SAMPLING OF THE ENTIRE WATER COLUMN IN ROUGH SEAS NEAR THE COAST

This year the Ocean Observatories Initiative (OOI) tested platforms for consideration at its 25m depth Oregon and Washington long-term observation sites. These sites are particularly challenging for moorings and cabled profilers that sample up to the air-water interface because wave heights at them annually exceed 1.5m mean depth. To reduce mooring line tension, OOI will deploy surface buoys that submerge under crests of large waves and which attach to anchors with elastic stretch hoses. A test mooring was successfully deployed for five months at OOI Inshore Oregon site with improvements based on prior testing. This platform, developed for OOI at the Woods Hole Oceanographic Institution, can support a large sensor suite at the top and bottom of the water column, but not along the stretch hose. Coastal surface piercing profilers (CSPPs) will fill this gap. This summer, CSPP technology was assessed with two concurrent month-long field demonstrations near OOI Inshore and Shelf Oregon sites. Results of the mooring's and profilers' mechanical performance are shown along with an illustration from these data of the scientific value these paired platforms will provide. (Abstract ID 12806)

GROWTH AND GRAZING MORTALITY OF NANO- AND PICOPLEANKTON IN THE SARGASSO SEA

The microbial loop mediates the transfer of carbon from primary producers to higher trophic levels in the ocean and thereby influences the potential of the system to export carbon. We investigated the growth of and grazing on different groups of phytoplankton, with special attention to Synechococcus, Prochlorococcus and pico-and nano eukaryotes in the Sargasso Sea utilizing the dilution method. The experiments were carried out at or near BATS (Bermuda Atlantic Time-series Station) during February and July 2011 in several depths in the euphotic zone. We analyzed the plankton community change during the incubations by measuring chlorophyll a and changes in cell abundance by flow cytometry (FCM) and epifluorescence microscopy. Some experiments were nutrient amended and we observed significant enhancement of growth and sometimes of grazing rates in the upper mixed layer. Growth and grazing on Synechococcus was enhanced positively by nutrient amendment, indicating their potential in responding to short term nutrient injections. We will be reporting group specific production and grazing and will discuss their seasonal variability in the context of the production regime of the Sargasso Sea. (Abstract ID 12227)

A CONSERVATION-BASED GROUP RESEARCH PROJECT IN A REQUIRED UNDERGRADUATE LABORATORY COURSE

While learning standard research techniques, undergraduates in a marine biology laboratory class at Hawai'i Pacific University collect “citizen science” data in group research projects. In 2010, students collected data on coral and seaweed percent cover and diversity in the Waikiki Marine Life Conservation District (MLCD). This data, together with similar data collected by undergraduate interns, will be used to validate a community-based volunteer monitoring project in the Waikiki MLCD and help with resource management in the area. Although all science laboratory classes constitute active learning, this project was a good way to train students on how to conduct rapid ecological assessments using a quantitative photo quadrant survey method while simultaneously providing conservation-based applications for the data. The group project involved both field and computer-based image analysis components. (Abstract ID 12617)

IN-SITU MEASUREMENTS WITHIN MOBILE BED LAYERS WITH “ELECTRONIC PEBBLES”

In-situ measurements of the mobile bed layer are now possible with new state-of-the-art micro-electronic machines (MEMEs). These electronic pebbles (ePebbles) are 2.8x1.5x1.4 cm and are equipped with 2 tri-axial accelerometers, battery, and wireless transmitter. The plastic enclosure is comparable in size to coarse gravel. The size and density was chosen based on mobility criteria for small-scale flumes. We are testing the ePebbles in a laboratory wave facility to explore the incipient motion of a sediment bed and relate it to the combination of shear stress and pressure gradients that act on exposed particles. We hope experiments with these devices will provide significant insight into incipient motion and sediment transport under free-stream and oscillatory flow fields in the nearshore environment. TOWARD ESTIMATING THE PAN-ARCTIC DIVERSITY OF EUKARYOTIC MICROBIAL PLANKTON

Microbial plankton play a pivotal role in the polar ecosystems, characterized by the complex mixing of Pacific and Atlantic waters into the Arctic Ocean. However, their taxonomic diversity has been relatively unstudied. This study will provide metagenomic description of eukaryotic microbial diversity in the Barents, Beaufort and Beaufort Seas, which all are undergoing changes in sea ice cover. Samples were collected from contrasting depths, hydrographic regions and seasons. In the Barents Sea, collections were made in May 2010 and June 2011 in open Atlantic-influenced waters, ice-covered Arctic waters and at the Polar Front. In the eastern Beiring Sea, samples were collected in March 2010 from the shelf during a diatom bloom. In the Beaufort Sea, samples were obtained in July-August 2011 from ice-covered Beaufort Gyre waters from several depths down to 3,500 m. Short (ca. 350bp) segments of the 18S ribosomal DNA gene were amplified for 454 sequencing, which yielded from 3,000 to 10,000 sequences from each of the ten community samples. Initial analyses revealed common generic elements among all water masses but with strikingly different relative abundance profiles. (Abstract ID 11686)

HORIZONTAL AND VERTICAL PROCESSES CONTRIBUTING TO NATURAL IRON SUPPLY IN THE MIXED LAYER IN THE ONA BASIN IN SOUTHERN DRAKE PASSAGE, ANTARCTICA

Natural iron fertilization in the Ona Basin is driven by a variety of physical processes, including lateral advection, vertical mixing, and mixed-layer entrainment. Comparison of sea surface height and Chl-a concentrations for the years 1997-2010 shows >95% correlation between Chl-a levels and lateral advection of iron-rich waters during November and December. However, no significant correlations are found from January through April, even though high Chl-a levels persist through March. Comparison of Chl-a and zonal wind stress shows a similar correlation pattern, suggesting that lateral transport alone cannot support the bloom after December. Vertical mixing and mixed-layer entrainment are considered as additional mechanisms for delivering iron into the Ona Basin mixed layer to sustain the bloom. Estimates of iron flux based on cruise data from summer of 2004 and winter of 2006 suggest that mixing can supply iron to the base of the mixed layer at a rate of 96 ± 9 nmol m⁻² day⁻¹ in the winter and 64 ± 2 nmol m⁻² day⁻¹ in the summer. In addition, the summer mixed layer in Ona Basin deepens from January into April, allowing for additional iron entrainment. Numerical simulation indicates that mixing and entrainment combined can supply 176 ± 44 nmol m⁻² day⁻¹ into the top 30 m from January to April, which is believed sufficient to sustain the bloom that throughout the summer. DYNAMICS AND STOICHIOMETRY OF NUTRIENTS AND PHYTOPLANKTON IN WATERS INFLUENCED BY THE OXYGEN MINIMUM ZONE IN THE TROPICAL SOUTH EAST PACIFIC

The tropical South East Pacific is characterized by strong coastal upwelling on the narrow continental shelf and an intense oxygen minimum zone (OMZ) in the intermediate water layer. These hydrographic properties are responsible for a permanent supply of water rich in nutrients and with a remarkably low inorganic N:P stoichiometry to the surface above the shelf. We investigated the impact of OMZ-influenced upwelling waters on phytoplankton growth, elemental and taxonomical composition, by collecting data for hydrographic and biogeochemical parameters along an east-west transect at 10°S off Peru, stretching from the...
upwelling region above the continental shelf to the well-stratified oceanic section of the eastern boundary regime. New production in the area of coastal upwelling was driven by large-sized phytoplankton with a generally low N:P ratio (16:1). A deep chlorophyll maximum consisting of nano- and microphytoplankton occurred in the shelf-open ocean transition zone above the shelf break and featured intermediate N:P ratios close to Redfield proportions. High PON/P (20:1) was observed in the stratified open ocean, coinciding with the abundance of the pico-cyanobacterium Prochlorococcus. Excess phosphate (P\textsuperscript{ex}) present along the entire transect did not stimulate growth of nitrogen-fixing phytoplankton. Instead, a large fraction of P\textsuperscript{ex} generated within the OMZ was consumed by non-Redfield production of large phytoplankton in shelf surface waters. (Abstract ID 9688)

MICROZOOPLANKTON GROWTH AND HERBIVORY PATTERNS ACROSS A TEMPERATURE GRADIENT IN THE BARENTS SEA

Microzooplankton play a pivotal role in the ocean, but their response to climate change in the Arctic remains to be understood. A set of shipboard experiments was conducted in the Barents Sea between 70°N and 79°N in 2010-2011 to examine the hypothesis that microzooplankton growth and grazing rates will be enhanced in warmer open waters as opposed to cold ice-covered waters. The maximum growth rates of 27 predominant morphospecies ranged between 0.27 and 1.83 d\textsuperscript{-1} and were weakly related to sea temperature. In the polar waters east of Svalbard (-1.8 to 0.0°C) ciliates grew faster (up to 200%) than predicted by several published equations relating their intrinsic rates to the cell volume and temperature, whereas in the Atlantic waters off the north coast of Norway (5.0 to 8.6°C) their growth rates were close to predicted. Microzooplankton community herbivory rates increased with temperature (p<0.05), but their maximum impact on primary production (over 100% removed daily) was observed within the Polar Front (1.0 to 4.0°C). The potential confounding effects of phytoplankton prey composition and internal predation within microzooplankton communities will be considered. (Abstract ID 12843)

DIRECT OBSERVATION OF SUBTROPICAL MODE WATER CIRCULATION IN THE WESTERN NORTH ATLANTIC OCEAN

Eighteen Degree Water (EDW) is the dominant mode water of the North Atlantic subtropical gyre and an interannual reservoir of anomalous heat, nutrients and CO\textsubscript{2}. Although isolated beneath the stratified upper-ocean at the end of each winter, EDW may reemerge in subsequent years to influence mixed layer properties and consequently air-sea interaction and primary productivity. We report on recent and unique direct measurements of EDW circulation and stratification in the western subtropical gyre using an array of 40 acoustically-tracked, isotherm-following, bobbing profiling floats. These subsurface drifters, programmed to track and intensively sample the vertically-homogenized EDW layer, reveal convoluted circulation pathways and coherent features unresolved by previous studies. EFFECTS OF THE APRIL 2010 DEEPWATER HORIZON CRUDE OIL SPILL ON OFFSHORE SEAWEED DIVERSITY IN THE NW GULF OF MEXICO

Results from three post-spill dredging expeditions aboard the R/V Pelican indicate that seaweed diversity in all dredged sites offshore LA, MS and AL was severely depressed relative to pre-spill sampling. Whereas Ewing Bank (~28°51’70”N, 91°01’289”W) was one of the northern Gulf’s most algal diversity-rich sites pre-spill, only a limited number of benthic species - characterized by surface cell layers that can slough off or are embedded in a gelatinous matrix- were dredged at this site in Dec. 2010. Species diversity at Ewing Bank had increased to 20 during April 2011, but subsequently had significantly declined during August 2011. Rare or partly algal-derended unconsolidated rubble retrieved from the 2011 cruises have been maintained in salt-water tanks in our lab, and the subsequent rate and diversity of algal colonization on these rocks documented. In addition to our ongoing biodiversity research, in the future we plan to characterize the transcriptome of carefully selected taxa in order to assess how offshore seaweeds respond to and recover from hydrocarbon insult. Funding by NSF (RAPID grant) and GSI RFP-III to Frederico (seaweeds) and Felder (macrocrustaceans). (Abstract ID 10034)

FUTURE OCEAN MEASUREMENTS FROM SPACE

Seasat, launched by the U.S. National Aeronautics and Space Administration (NASA) in 1977, was the first dedicated ocean-viewing satellite. Since then NASA, the European Space Agency, France’s Centre National d’Etudes Spatiales, the Indian Space Research Organization, the Japan Aerospace Exploration Agency, and the China National Space Administration have all launched ocean-viewing sensors or dedicated ocean viewing satellites. Properties currently measured from space are sea surface temperature, topography (height), salinity; significant wave height and wave spectra; surface wind speed and vectors; ocean color; continental and sea ice flow, deformation, thickness; ocean mass; and to a lesser extent, surface currents. By 2025 one additional measurement will likely become available – total surface currents – but the largest foreseen improvements are increased spatial and temporal resolution and increased accuracy for all the currently measured properties. This study is based on Freeman et al., Ocean Measurements from Space in 2025, Oceanography, 23 (4), 144-161, 2010, with some updates. (Abstract ID 9723)

GLIDER OBSERVATIONS OF BIO-OPTICAL PROPERTIES IN THE COASTAL WATERS OF THE SANTA BARBARA CHANNEL, CALIFORNIA

Characterizing and understanding the vertical, temporal and spatial variability of coastal water processes at small regional and short time scales requires frequent sampling and integration of multiple data sources to support observations. Here we present repeated glider observations of relevant oceanographic properties, including temperature and salinity, chlorophyll fluorescence, optical backscattering and dissolved oxygen, across 2 target areas of the Santa Barbara Channel: along the Santa Barbara shoreline (a saw-tooth deployment of ~7 days each, 1-3km offshore, 0-50m deep), ideal to observe the scales of diurnal variability and the effect of episodic processes such as buoyant plumes, as well as a 4-km cross-shelf mission. We compared individual transects to satellite imagery for the period. The dense sampling allowed inferences about the scales of variations in net primary productivity, as well as indicated the potential of using glider data to understand phytoplankton response to quick variations in environmental conditions. (Abstract ID 10630)

EVALUATING THE FATE AND EFFECTS OF THE DEEPWATER HORIZON OIL SPILL ON WATER COLUMN BIOTA

The Deepwater Horizon oil spill in the northeastern Gulf of Mexico was not only the largest oil spill in US history, but unprecedented amounts of dispersants were applied both at the subsurface release-point and in surface waters to entrain the oil into the water column with the intention of reducing impacts to wildlife and shorelines. The enhanced entrainment and reduction in dispersed oil droplet sizes caused by dispersant use would be expected to increase water column biota impacts. Thus, evaluation of impacts to water column biota is of particular interest for this spill and in consideration of the risks associated with future deepwater blowouts. Oil fate and effects modeling is being used to quantify water column impacts in support of claims for natural resource injuries being developed by natural resource trustees. The on-going modeling analysis involves considerations of current data and/or hydrodynamic modeling at a range of scales; oil fate modeling, exposure and toxicity analysis, fish and invertebrate distributions, and population modeling to determine long-term effects. The approach and supporting data collections being developed for this analysis will be presented. (Abstract ID 12869)

ON THE IMPACT OF EDDIES ON THE SOUTHERN OCEAN CHLOROPHYLL DISTRIBUTION

The Southern Ocean is a region of intense eddy activity, yet the long-term mean influence of eddies on biological productivity and biogeochemistry is poorly known. To study this influence, we identified and tracked over 100,000 eddies including their associated chlorophyll-a (CHL) based on satellite observations of sea level anomalies and CHL from 1997 to 2010 south of 35°S. This gave us an excellent mean statistics despite missing values in CHL of 45%. We find that eddies account for 25% of the total CHL on average, highlighting their potential role in the climatological distribution of CHL in the Southern Ocean. Secondly, our analysis reveals a significant mean negative CHL anomaly of about -4% for anticyclones versus a mean positive anomaly of 2% for cyclones compared to the climatological CHL, however with some spatial variability: cyclones as well as anticyclones contain anomalies of opposite sign in the core of the Antarctic Circumpolar Current (ACC) compared to both, north or south of it. The net effect of these anomalies for instance in the ACC is a CHL increase of about 2%. (Abstract ID 10975)

A CLIMATIC PULSE IN THE HEART OF THE OXYGEN MINIMUM ZONE

Oxygen (O2) is a critical constraint on marine ecosystems. As oceanic O2 falls to hypoxic concentrations, habitability for aerobic organisms decreases rapidly. We show that the spatial extent of hypoxia is highly sensitive to small changes in the ocean's O2 content, with maximum responses at suboxic concentrations where anaerobic metabolisms predominate. In model-based reconstructions of historical oxygen changes, the world's largest suboxic zone, in the Pacific Ocean, varies in size by a factor of two. This is attributable to climate-driven changes in the depth of the tropical and subtropical thermocline which have multiplicative effects on respiration rates in low-O2 water. The same mechanism yields even larger fluctuations in the rate of nitrogen removal by denitrification, creating a link between decadal climate oscillations and the nutrient limitation of marine photosynthesis. LIGHT TRANSMISSION THROUGH OCEAN WATERS BENEATH MELT-SEASON SEA ICE IN THE CHUKCHI AND BEAUFORT SEAS

The Chukchi and Beaufort Seas have experienced significant declines in sea ice over recent decades, including reductions in thickness as well as seasonal duration of sea ice cover. These changes in sea ice have important cascading impacts on the physical, biological, and biogeochemical state of the overall marine environment throughout the region. Here, we present observations of light transmission through the top 30–50 meters of ocean waters beneath both ponded and upwelled sea ice surfaces, collected at nineteen sites in the Chukchi and Beaufort Seas during the NASA ICESCAPE missions in June-July of 2010 and 2011. The transmission of light to the upper ocean was found to be spatially heterogeneous and dependent on wavelength, ice thickness, and the areal and vertical distribution of bare ice and melt ponded surfaces. In particular, light transmission through ponded ice was up to four-fold greater than through upwelled ice, although these differences dissipate and become negligible with depth. The complex under-ice radiation fields are additionally presented in the context of a suite of biogeochemical properties of both the ice and under-ice water column. (Abstract ID 12741)

ASSESSMENT OF A REDUCED RANK SMOOTHER IMPLEMENTATION WITH A 1/4 DEGREE OCEAN MODEL

Retrospective data assimilation methods such as 4Dvar or smoothers designed after Kalman’s DEGREE OCEAN MODEL suggest the upper 10-15 cm of each core may record a single depositional event, possibly along the axis of the bedform field. Distinct physical structures and radioisotopic signatures excess of 100 m, and are likely the product of density currents associated with large floods of the Stehekin River, or slope failures on the delta front. Radioisotope, x-ray, and grain-size analysis of NEMO (Nucleus for European Modelling of the Ocean), highlighting its attractive additional computation complexity when it is implemented with an already-existing Kalman filter. The smoother is then assessed through twin data assimilation experiments involving realistic observation types and density. It is shown that the smoother further reduces the errors that remain in the state estimates after the filter pass. Moreover, the smoother estimates can be advantageously used to obtain observation-constrained model’s trajectories over limited time intervals, as 4Dvar does. Other benefits, but also caveats, will be presented. (Abstract ID 12021)

BEHAVIORAL ECOLOGY OF GOLIATH GROUPER SPAWNING AGGREGATIONS

The goliath grouper, Epinephelus itajara, is the largest group fish in the Atlantic ocean. E. itajara is extremely vulnerable to overfishing due to slow growth, long life, late sexual maturity, strong site fidelity and formation of spawning aggregations. Juveniles (< 1.20 m total length) inhabit fringing red mangrove (Rhizophora mangle) shorelines and adults inhabit coral reefs, reef- rock ledges and artificial structures. Field-based research on spawning aggregations has been limited to incidental observations of E. itajara courtship behavior. Here, I used SCUBA-based fieldwork to investigate the behavioral ecology of E. itajara spawning aggregations off east Florida, during two spawning seasons. The spawning sites contained year-round residents (2-10 fish) and breeding season transients (up to 50 fish). Peak aggregation activity was limited to September and October. The shape of the aggregation significantly changed depending on oceanographic conditions and lunar cycle. It is unclear how timing of arrival, aggregation persistence and aggregation response to environmental conditions affect reproductive output, but these results strongly suggest that the spawning aggregation is not a structure as rigid as previously thought. (Abstract ID 12654)

INTERNAL WAVE GENERATION AND VARIABILITY OVER ROUGH TOPOGRAPHY

Rough topography can promote mixing within the water column, and the intensity of the mixing varies with background flow. To quantify this mixing, an intense study was conducted at East Flower Garden Bank, part of the National Marine Sanctuary system. In addition to long-term instrumentation including acoustic Doppler current profiles (ADCPs) and temperature and salinity (TS) strings, short-term moorings were deployed for approximately ten days during the summer of 2011. These included 5 upward-looking ADCPs and one downward-looking ADCP each with a one-minute sampling frequency over and around the bank, and two TS string moorings that sampled every minute both over the bank and to the east of it. The string moorings had vertical spacing of approximately 10 meters. Additionally, either high-frequency pressure instrumentation or a wave-tide gauge was collocated with each ADCP. This suite of high-frequency measurements has allowed characterization of high-frequency internal waves over and around the bank, including spatial variability and changes relating to background flow conditions. High-frequency wave amplitudes were elevated northeast of the bank during the mixing experiment. (Abstract ID 9977)

LINKING DAETETIC AND DEEP-WATER SEDIMENTATION IN LAKE CHELAN, WA

The connection between deltaic and deep-water sedimentation is examined in Lake Chelan, WA, where external forces (e.g. tides, waves) have a negligible effect on sediment dynamics. Characterizing the linkage between these two environments provides an important boundary condition for understanding and modeling both nearshore and deep-water depositional systems. A detailed bathymetric and sub-bottom survey of the delta top, foreset, and adjacent deep-water setting reveals a largely muddy foreset biected by a tongue of large-scale (h = 2-10 m, λ = 20 m) bedforms. These sandy bedforms extend roughly 1 km down lake into water depths of excess 100 m, and are likely the product of density currents associated with large floods of the Stehekin River, or slope failures on the delta front. Radiocarbon, x-ray, and grain-size analysis of six gravity cores flanking the bedforms indicate that sedimentation is episodic and focused along the axis of the bedform field. Distinct physical structures and radiocarbon signatures suggest the upper 10–15 cm of each core may record a single depositional event, possibly the 100-year flood of the Stehekin River in 2006. (Abstract ID 10661)
FAUNAL DIVERSITY IN THE WORLD’S OXYGEN MINIMUM AND CARBON MAXIMUM ZONES

Oxygen minimum zones (OMZs) have high dissolved inorganic carbon concentrations (Paulmier et al. 2011) and varying temperatures, making them useful models for study of changing ocean environments. Where OMZs intersect margins the benthic faunas are known to exhibit reductions in macrofaunal abundance, altered composition, decreases in species richness and increases in dominance below oxygen concentrations of 0.1-0.2 ml/l (5-10 μmol/ kg). While oxygen has been interpreted as the primary driver of macrofaunal diversity patterns in these regions, we ask how fauna respond to the corresponding carbonate chemistry trends using international DIC and O2 databases. Cross-margin transect data from the NE and NW Arabian Sea, OR, CA, Peru, and Chile suggest that at bathyal depths, oxygen drives abundance and diversity patterns whereas carbonate chemistry may have greater influence on taxonomic composition. Carbonate chemistry differs among OMZs due to regional differences in T, S, alkalinity and depth; saturation states of calcite and aragonite within the OMZ are highest in the Arabian Sea and decrease from Peru to Oregon to California. Faunal patterns across OMZs may offer insight into ocean ecosystems of the future. (Abstract ID 12190)

RESULTS OF THE US IOOS TESTBED FOR COMPARISON OF HYDRODYNAMIC AND DISSOLVED OXYGEN MODELS OF THE CHESAPEAKE BAY

Results from multiple 3-D hydrodynamic and dissolved oxygen models for Chesapeake Bay have been compared to each other and to EPA monitoring data for the years 2004 and 2005. On seasonal time-scales, the models all do well in capturing fundamental aspects of the hydrodynamic and oxygen fields, although the intensity of the pycnocline is underestimated. Models with constant net respiration independent of nutrient supply reproduce hypoxia nearly as well as much more complex, nutrient-dependent ecological models. Seasonal variation in DO was insensitive to seasonal cycles in the respiration rate, freshwater input, and density stratification. Rather, seasonal variation in DO was found to be very sensitive to seasonal variations in the wind, likely due to seasonal variations in the nature of wind-induced lateral and longitudinal advection. The overall intensity of stratification and resulting hypoxic volume was also found to be sensitive to numerical formulations of turbulence closure and advection. Another significant finding with regards to future modeling strategies is the result that the ensemble hindcast for dissolved oxygen using multiple models was more accurate than the hindcast from any one model. COASTAL CARBON FLUXES ALONG THE U.S. EASTERN CONTINENTAL SHELF DERIVED FROM A COUPLED BIOGEOCHEMICAL-CIRCULATION MODEL

The role of coastal margins in regional and global carbon budgets is not well understood, primarily because many key shelf fluxes are not yet well quantified over annual time scales, e.g. the exchange of carbon across the land-ocean and shelf-slope interfaces, air-sea exchange of CO2, burial, and biological processes including productivity. Because of the temporal and spatial undersampling typically associated with most observational studies, model-derived carbon flux estimates are likely to be the only viable approach for defining these fluxes in a consistent manner on annual time scales. A primary goal of our USECoS (U.S. Eastern Continental Shelf carbon cycling) project is to estimate coastal carbon fluxes in this region using models quantitatively evaluated by comparisons with observations. Our preliminary carbon budget for this region suggests that the USECoS region is a sink of atmospheric CO2. In

SOLAR ROBOTIC MATERIAL SAMPLER SYSTEM FOR ADAPTIVE SAMPLING OF CHEMICAL, BIOLOGICAL AND PHYSICAL PARTICLES

Visible ecosystem impacts of events such as oil spills and HAB blooms receive most of the attention from the public. However, oil, HABS and other types of accidental contaminants, such as radioactive particles, have fundamental impacts on less-visible portions of delicate chemical and biological ecosystems. How to respond to an event in a timely fashion? How to track the dynamically changing distribution of contaminants through the water column? Where and how are the contaminants dispersed? These key questions need to be addressed over large spatial dimensions and over long time frames. This paper describes the development of an autonomous robotic sampling platform, deployable for long-term monitoring missions and capable of collecting samples to track contaminant dispersion. The system is a fusion of a sensor-equipped AUV with a robotic sampling platform for adaptively sampling the water column. Field samples taken are analyzed shore side using lab-based analytical instrumentation. Lastly, the mobile sampler system can be guided by remote sensing data for focused sampling of wide area dispersions. (Abstract ID 12047)

ANTHROPOGENIC OCEAN HEAT AND CARBON UPTAKE IN CMIP5 EARTH SYSTEM MODELS: THE ROLE OF SYSTEMATIC AND RANDOM UNCERTAINTY

A new set of Earth System Models (ESM) show that the Southern Ocean (SO) south of 30°S absorbs on average 70% of anthropogenic heat and 42% of anthropogenic carbon, indicating that the SO thus plays a central role in determining the rate of climate change. However, the exact processes determining the magnitude and regional distribution of heat and carbon uptake remain poorly understood with models showing the largest disagreement in the SO due to their widely divergent representation of physical circulation and atmosphere-ocean interactions. Indeed, the fraction of the simulated uptake within the SO ranges between 30 to 160% for excess heat and between 38 to 47% for anthropogenic carbon. Natural unforced variability in models and observations further complicates the detection and attribution of changes. We compare heat and carbon uptake in CMIP5 ESAs using an analysis framework that includes both novel skill-score metrics and investigations in density spaces. We assess the contribution of internal variability to model-model and model-data differences by using an ensemble of six simulations with different initial conditions of a single ESM. COMPACT OCEAN MODELS ENHANCE ONBOARD AUTONOMY OF UNDERWATER VEHICLES

Underwater vehicles are typically centrally controlled from shore, limiting their ability to adapt to new observations which would inform more effective sampling strategies. This inflexibility stems from the intermittency of communications and low bandwidth between shore and submerged mobile platforms. To enable greater autonomy for underwater vehicles, we developed a compact ocean modeling and assimilation system that can be deployed on-board of an underwater vehicle. The developed system estimates a synthetic picture around the vehicle by assimilating data from the vehicle undereway system. As a result, we bypass communication bandwidth and delay limitations by assembling both synoptic and local data on a vehicle. The developed modeling system is based on a statistical model that is trained to emulate the dynamics of surface currents observed by HF-Radar. Our statistical model reduces spatial complexity using empirical orthogonal functions (EOF) and captures the dynamics of the EOF coefficients using an autoregressive model. Our statistical model was trained using two years of HF-Radar observations off Monterey Bay, California. Our data assimilation system is implemented using a reduced-dimension Kalman filter that operates in the EOF space. We test the performance of the system in a series of computational experiments, where we assimilate underway velocity measurements to optimize transit time for an AUV deployed off Monterey California. LARGE-EDDY SIMULATION OF BREAKING INERTIA-GRavitY WAVES

Inertia-gravity wave breaking is an important process in maintaining the general circulation in both the atmosphere and the ocean. However, its dynamics are still not sufficiently well
understood, in part because the wide range of length scales involved, from the wavelength of the wave and the primary instability structures to the turbulent small scales where energy and momentum are dissipated, make numerical simulation difficult. We investigate inertia-gravity wave breaking using a novel form of Large-Eddy Simulation (LES), performed using the Adaptive Local Deconvolution Method (ALDM), wherein the truncation error in the discretization of the governing equations is tuned so as to function as an implicit sub-gridscale turbulence parameterization. Although tuned for three-dimensional homogeneous isotropic turbulence, it has proved effective also for stratified flows. The initial conditions for the simulations are obtained from linear stability analysis (normal mode and singular vector analysis) of monochromatic inertia-gravity wave solutions. Both low- and high-frequency waves, with amplitudes both above and below the threshold for static stability, are considered. The ALDM results are compared to standard LES schemes and to direct numerical simulations. (Abstract ID 12212)

DECADAL VARIABILITY IN THE THERMOCLINE OF THE AZORES FRONT REGION AND ITS IMPACT ON DEEP OCEAN PARTICLE FLUX

29 years of daily temperature and current data from the deep-sea mooring site KIEL276 in the subtropical northeast Atlantic (33°30′N, 22°W) between 1980 and 2009 were used to study decadal variability in the permanent thermocline (240 m and 500 m). Both the temperature and the current velocities and directions show significant differences between the three decades. In the 1980s, the temperature decreased resulting in the 1980s being the coldest decade. An increasing trend in 1990s was observed leading to the warmest decade in the 2000s with a strong temperature gradient in the last years. Inter-decadal variability in the currents was seen with relatively weak currents in the 1980s and 2000s but intensification in the 1990s pointing to a displacement of the North Atlantic Subtropical Gyre. North- and southward propagation of the Azores Front, which separates the colder northern water from warmer Sargasso Sea water, leads consequently to frequent changes in the biological environment over the mooring position, which is revealed in mass flux derived from a sediment trap in 2000 m from 1994 to 2008. TRACING THE CARBON LINKAGES BETWEEN MISSISSIPPI RIVER NUTRIENT INPUTS AND HYPOXIA FORMATION ON THE LOUISIANA CONTINENTAL SHELF

Nutrients from the Mississippi River traditionally have been viewed as fueling summertime hypoxia across the Louisiana continental shelf. But recent modeling assessments offer a contrasting view; that non-riverine carbon sources are important fuels because the shelf strongly exports nutrients and carbon to deep offshore waters. These contrasting views were investigated during annual 2007-2011 July shelfwide cruises. Measurements of surface dissolved inorganic carbon (DIC) indicate largely balanced community production (P) and respiration (R) for most of the shelf, except in nearshore low-salinity (<25) areas most strongly influenced by river inputs. In these nearshore areas, DIC loss from surface waters rather closely matched results expected for complete nutrient uptake by phytoplankton and sedimentation of phytoplankton carbon to bottom waters. These results indicate a system that is strongly retentive for river nutrients and carbon, with little leaky offshore export. Investigations also suggest a new coupled physical-biological model for hypoxia formation based on low-oxygen waters spreading from nearshore hotspots of carbon cycling. (Abstract ID 11061)

ADAPTATION OF THE MARINE CYANOBACTERIUM TRICHOCESIDIUM TO ELEVATED CO2

Elevated CO2 has been shown to stimulate N2 fixation in the marine N2 fixing cyanobacterium Trichodesmium, but published studies have generally used cultures acclimated under high CO2 conditions for only a few generations. To examine the potential for long-term adaptation, we cultured 6 replicate cultures of Trichodesmium at 380 and 750 ppm CO2 for more than 3 years. Physiological parameters, elemental ratios, and gene expression were then measured in both adapted treatments, as well as in adapted cultures switched to the opposite CO2 treatment (750 to 380 and 380 to 750). Even after ~50 generations N2 fixation rates were still significantly higher in high CO2 treatments; surprisingly, these high CO2-adapted cultures also continued fixing N2 at increased rates even when returned to 380 ppm growth conditions. Trends in growth rates were similar to those for N2 fixation, but CO2 fixation trends differed. Transcriptome samples are currently being analyzed for all treatments. Results will be discussed in terms of the potential for adaptation of Trichodesmium to elevated CO2 in the future acidified ocean, and the consequences for the marine N cycle. (Abstract ID 12105)

TURBULENCE DISSIPATION RATE AND MIXING ON THE LAN-YU RIDGE OF THE LUZON PASSAGE

The waters of the Luzon Passage are among the most energetic environments in the global ocean. Tidal currents as large as 0.8 m/s and strong stratification over the steep ridge topography give rise to internal wave generation, driving baroclinic currents. In addition, the Kuroshio Current often drives strong flow through the area. Not surprisingly, this environment supports exceptionally turbulent energy levels distributed over full depth, leading to mixing between the South China Sea and Kuroshio water masses. Here, we present the first full-depth, direct measurements of turbulence along the Lan-Yu Ridge of the Luzon Straits over a spring neap cycle of tidal forcing. Data were collected on the east and west slopes of a ridge crest suggested by model results to be the site of exceptional baroclinic conversion of the barotropic tide. Measurements at each of these locations show that the strongest turbulence levels occur during the phase of the flood-ebb cycle when flow is in the downwelling direction, indicating either hydraulic or slope convection processes. Our analysis shows very large turbulence levels, with dissipation rates reaching 10^-5 W/kg at 1000-m depth, and depth-integrated dissipation rate levels reaching 1 W/m2. This implies that at least 10% of the locally generated baroclinic energy is dissipated directly before radiating away and suggests that local turbulent processes have considerable impact on the internal wave generation occurring at this region. TURBULENCE-INDUCED SINKING AND SUBSTRATE TYPE IMPACT SETTLEMENT PATTERNS OF OYSTER LARVAE

Feedbacks between turbulence-mediated larval behavior and substrate roughness could influence the distance that larvae travel before contacting the bottom from a given height, known as the “hitting distance.” These feedbacks may be particularly important for oyster settlement, because oysters naturally form discrete patches of reef that are rougher than restored reefs or surrounding mud flats. Here we estimated the hitting distance for oyster larvae (Crassostrea virginica) settling over four different substrate types: mud, natural reefs, and restored reefs constructed from oyster or whelk shell. Larval behavior was modeled using laboratory data on the responses of larval oysters to turbulence dissipation rate. Flow velocity and turbulence profiles were based on measurements collected in coastal Virginia. These measurements were integrated with McNair’s Hitting-Distance model to calculate the larval probability of contacting the bottom as a function of downstream distance. Within an average reef patch length of 30 m, the cumulative probability of hitting bottom was highest over natural reefs (natural reef > whelk shell > mud > oyster shell). Results suggest that substrate roughness is important for successful oyster reef restoration. (Abstract ID 10571)

BENTHIC FLUXES ON THE OREGON SHELF

Benthic chamber experiments were performed on the Oregon shelf at 50-150 meters depths in June and August 2009. Similar oxygen fluxes between eddy correlation and benthic chamber techniques in permeable sediments indicate limited pore-water advection. In chamber incubations, oxygen and nitrate fluxes were into the sediments while silicate, iron and ammonium fluxes were out. Benthic fluxes were similar in value and sign to those from Washington and California. Water 3 meters from the bottom was consistently hypoxic (-52 µM O₂) and had ammonium concentrations up to 5.4 µM. Given measured ammonium fluxes, it would take several months to achieve such high bottom water concentrations. Benthic oxygen fluxes (-4.7 to 13 mmol/m²*d) were sufficient to draw down bottom oxygen concentrations by 15% per month. Iron fluxes (average of 8 µmol/m²*d) would increase bottom water concentrations up to 38% per month while loss of fixed nitrogen (-0.8 to -3.4 mmol/m²*d NO₃ and 0 to +1.2 mmol/m²*d NH₄) due to denitrification in the sediments, decrease nitrate concentrations by 3-5%. Thus, benthic fluxes, in the net, increase primary productivity in this upwelling system. (Abstract ID 10594)
AUTOTROPHIC DENITRIFICATION FOUND IN THE BOSPORUS PLUME OF THE BLACK SEA

Autotrophic denitrification was measured in the southwest coastal Black Sea where the Bosporus Plume injected oxidized chemical species (especially O₂ and NO₃⁻) into the oxic, suboxic and anoxic layers of the Black Sea. To determine the bacterium responsible for autotrophic denitrification, depth profiles of three autotrophic bacteria, members of the SUP05 and BS-GSO2 groups of gammaproteobacteria and the epsilonproteobacterium Sulfurimonas, were examined. Sulfurimonas (BS139) was the most likely to mediate autotrophic denitrification. Anammox activity was not detected at that station though low levels of Scalindua DNA were present. These results provide evidence for a modified ecosystem and different N cycling. These findings, particle-attached N and S pathways should be examined in oxygen deficient waters such as the Black Sea and oxic oxygen minimum zones. (Abstract ID 11682)

INFLUENCE OF THE EXTRATROPICAL OCEAN CIRCULATION AND SURFACE HEAT EXCHANGE ON THE TROPICAL CLIMATE IN A SECTOR COUPLED CLIMATE MODEL

This study shows that induced MOC hemispheric asymmetry causing interhemispheric asymmetry in extratropical surface ocean heat exchange can control aspects of tropical circulation and the position of ITCCZ. We aim to further understanding of key mechanisms hence we employ an intermediate complexity coupled climate model derived from GFDL CM2.5. Through a set of modular simplifications in sector geometry, configuration with closed rectangular ocean randomly places the dominant deep-water production and heat release in one hemisphere. Advection and convective feedbacks in extratropical ocean cause this forced hemispheric symmetry breaking that leads to positioning of ITCCZ in the MOC dominant hemisphere. Opening of circumpolar channel in subpolar region of MOC dominant hemisphere reduced ocean heat release there due to decrease of OHT and expansion of sea ice. This forced hemispheric symmetry breaking moves the dominant region of deep-water circulation and the position of ITCZ. We aim to further understanding of key mechanisms as asymmetry in extratropical surface ocean heat exchange can control aspects of tropical circulation and the position of ITCCZ. We aim to further understanding of key mechanisms hence we employ an intermediate complexity coupled climate model derived from GFDL CM2.5. Through a set of modular simplifications in sector geometry, configuration with closed rectangular ocean randomly places the dominant deep-water production and heat release to opposite hemisphere that causes shift of ITCZ across the equator. Overall, in this simplified coupled system, ITCCZ is always downstream (upstream) of the cross-equatorial OHT (AHT) controlled by hemispheric asymmetry in extratropical ocean circulation and surface heat exchange. (Abstract ID 12616)

A high resolution ice-ocean coupled model is configured for the northern Sea of Okhotsk to simulate the transport of the dense shelf water produced in the coastal polynyas. However, the nearshore process of larval transport is not well understood. In the summer 2010, physical data and biological samples were collected at the surf zone in Sand City, CA. Preliminary results show that concentrations of barnacle larvae were higher in the rip current than in the surf zone ridge. Phytoplankton was also more abundant in the rip current than in the surf zone ridge. The differences between the rip and the rip concentrations were greater with the phytoplankton than zooplankton. This might be partially explained by the sinking behavior of larvae in turbulence. We simulated this mechanism using bio-physical coupling method. The collected benthos data were used for initializing the surf zone hydrodynamic model by Delt3D. The flow velocities and dissipation rates from the physical model were then transferred to a biological model to investigate the role of turbulent flow in the behavior and transport mechanism of barnacle larvae. The combined simulation method can be useful for further investigation of larval transport mechanism. (Abstract ID 12515)

ICE-OCEAN COUPLED MODEL WITH 1KM GRIDS TO STUDY THE DENSE SHELF WATER TRANSPORT IN THE SEA OF OKHTOKS

A high resolution ice-ocean coupled model is configured for the northern Sea of Okhotsk in order to simulate the transport of the dense shelf water produced in the coastal polynyas. Spatial resolution is 1km for the continental shelf region. The primitive equations and a z-o coordinate are used for the ocean part. The ice model consists of the dynamic process and the thermodynamic process. The ice internal stress is calculated based on the elastic-viscous-plastic rheology as well as ice rotation. The total stress is then calculated and applied to the ice model.

HORIZONTAL DISTRIBUTION OF PHYTOPLANKTON COMMUNITIES DURING LATE SUMMER IN THE WESTERN ARCTIC

TO THE NORTH ALONG 155ºE, A MIXED LAYER DEPTH (MLD) DEEPENED GRADUALLY, REACHING 104 M ON 15ºN AND THEN SHOAL ED AGAIN. THE TOP OF NITRACLINE WAS AT OR BELOW THE MLD AND DEEPEST (138m) ON 15ºN. IN THE LATITUDE OF 0–29ºN, THE DEPTH OF CHL A MAXIMUM (DCM) WAS DEEPER THAN THE TOP OF NITRACLINE AND WAS OBSERVED AT THE 2.4±1.3% LIGHT DEPTH (RELATIVE TO 0 m). THE PHOTOCHEMICAL EFFICIENCY (Fv/Fm) MEASURED WITH THE FRR FLUOROMETER HAS BEEN USED AS AN INDICATOR OF PHOTO-PHYSIOLOGICAL STATE, AND THE MAXIMAL DEPTH OF Fv/Fm WAS UNDERLYING DEEPER THAN THE DCM, AND CORRESPONDED TO THE 0.8±0.2% LIGHT DEPTH. HERE, WE DISCUSS THE RELATIONSHIP BETWEEN PHYTOPLANKTON DISTRIBUTION AND PHOTO-PHYSIOLOGICAL STATE, COMBINED WITH THE RESULTS OF PIGMENT COMPOSITION. (ABSTRACT ID 10788)
The response of phytoplankton community to recent environmental changes in the western Arctic Sea (the northern Chukchi Sea), especially shrinking of sea ice, was assessed. Phytoplankton groups based on HPLC phytoplankton pigments had been analyzed in the late summers of period 2008–2010. Steel-Dwass’ multiple-comparison tests were performed for some physical, chemical and biological parameters among the groups. We found significant difference in the distribution of surface phytoplankton community between the year of remarkable sea ice decline (2008) and other (2009 and 2010). Haptophytes and some other phytoplankton groups dominated and distributed widely in the surface layer during 2008 whereas prasinophytes or chlorophytes dominated in the light limited region spread in 2009 and 2010. This change in the phytoplankton communities is attributed to release from light limitation as a consequence of less sea ice in 2008. Expected long-duration of open water area spread during summer in the future may change biogeochemical cycle due to the shift of phytoplankton community in the western Arctic. (Abstract ID 12824)

DEPENDENCE OF THE AXES OF TROPOSPHERIC WESTERLIES AND STORMTRACKS ON THE LATITUDE OF AN EXTRATROPICAL OCEANIC FRONT AS REVEALED FROM IDEALIZED AGCM EXPERIMENTS

L latitudinal dependency of the thermal influence of an extratropical oceanic front on the atmospheric circulation is investigated through a set of perpetual AGCM experiments with zonally uniform SST prescribed at the model lower boundary. In each of the winter and summer hemispheres the latitudinal SST profile is characterized by a single front. Its latitude is varied systematically from one experiment to another while its intensity is unchanged. These idealized aqua-planet experiments reveal a climatological tendency for a storm track and eddy-driven polar-front jet (PFJ) in the lower troposphere to be organized near the SST front if located in the midlatitudes or subtropics, although this tendency is somewhat less evident in the upper troposphere. For the SST front located at a subpolar latitude, in contrast, eddy activity tends to be weaker and both the storm track and PFJ form equatorward of the front, as in another experiment from which the frontal SST gradient is removed and thus the influence of internal dynamics prevails. Sensitivity of the annual variability to the latitude of the SST front is also discussed. (Abstract ID 10178)

REAL-TIME PUBLIC AND STUDENT ENGAGEMENT DURING THE OCEAN OBSERVATORIES INITIATIVES VISIONS 2011 EXPEDITION TO AXIAL SEAMOUNT

The VISIONS11 expedition took place aboard the R/V Thomas G. Thompson with the remotely operated vehicle (ROV) ROPOS in support of the ongoing installation of the Ocean Observatories Initiative’s high-power and high-bandwidth cabled ocean observatory at Axial Seamount, a volcano on the Juan de Fuca Ridge that had erupted just 4 months prior. Here we describe our successes and lessons learned in engaging onboard scientists, students, and the public through the various outreach efforts employed during the expedition including: 1) live high-resolution video and audio streams from the seafloor and ship; 2) social media interactions; 3) direct connections to a science center and classrooms across the country; 4) an onboard immersion experience for undergraduate and graduate students; and 5) a routinely updated website. During the expedition, we had over 2.5 million hits on our website that hosted live high-resolution video and audio streams. Additionally, we interacted with over 500 followers across the globe through various social media sites while they were seeing active research in real-time. (Abstract ID 11756)

INTERANNUAL SURFACE FLOW VARIABILITY IN THE EQUATORIAL ATLANTIC OCEAN

Equatorial Atlantic surface currents between 5°S and 5°N derived by applying equatorial geostrophy to altimetric sea surface height data are combined with surface drifter and ARGO float surface drift velocities to investigate the time-space pattern of the interannual zonal surface flow variability. High baroclinic mode waves, so-called Equatorial Deep Jets (EDJ), were observed in moored current meter records obtained since 2002 at 0°N, 23°W. At a 4.5 year periodicity, they have harmonic amplitudes of more than 10 cm/s at intermediate depths and vertical wavelengths of about 400 m. These high-baroclinic-mode waves have smaller meridional scales compared to wind-generated low-baroclinic-mode equatorial waves. Using higher-order polynomials in the analysis of altimetric surface geostrophy which allows resolving similar scales at the surface leads to general good agreement between geostrophic zonal surface currents from altimetry and surface drift data. A 4.5 year period similar to the observed periodicity of EDJs at depths is found in the geostrophic zonal surface velocity data available since 1992 with maximum amplitudes of 2–10 cm/s located about 100 km north of the equator. A DETAILED LOOK AT COLD-VENTS USING HIGH-RESOLUTION AUV DATA: A MODEL OF GAS VENTING EVOLUTION ON THE NORTH CASCADIA MARGIN

The Northern Cascadia Margin has long been identified as a prolific gas hydrate province and has been studied for the past 25 years with a focus on the physical properties of hydrate-bearing sediments. In 2009, high-resolution bathymetry and sub bottom profiler data were acquired with the Dr. Allan B. AUV by MBARI. The data was collected in part to assist in navigating of the ROV (Doc Ricketts) during subsequent investigations of particular sites of interest, including Bullseye Vent, Spinnaker Vent, and hydrate outcrops at Barclay Canyon. The data allow for detailed mapping of surface, and shallow subsurface features associated with the onset, growth, and maturation of gas venting, gas hydrate, and seafloor chemosynthetic communities. Early degassing and arrival of chemosynthetic communities, early diagenesis and carbonate precipitation, formation of pockmarks, and mature fluid carbonate platforms barren of life are stages of observed venting. The results will assist in future IODP drilling, CORK installations, and understanding of time series work linking fluid expulsion to earthquake shaking. (Abstract ID 12292)

FLOCCULATION OF COLLOIDAL MONTMORILLONITE: A MODELING APPROACH

The physicochemical forces between individual sediment particles affect the strength of the bulk sediments. The same forces also influence the particle flocculation in the water column. Thus, the understanding of the flocculation processes allows the understanding of inter-particle forces in bulk sediments. We investigated the effect of organic matter (OM) on the flocculation of colloidal montmorillonite through laboratory experiments and computational flocculation modeling. The model, based on Smoluchowski coagulation model and population balance equation (PBE), was established with two key parameters, sticking efficiency and breakup parameter. The experiments tracked the temporal evolution of the floc sizes. The key parameters were calibrated through the interactive optimization of the model results against the laboratory results. The calibration showed that OM has a varying influence on the flocculation behavior. Xanthan gum does not influence flocculation, which is primarily determined by the DLVO interaction energies, whereas chitin modifies both the sticking efficiency and breakup parameter. This study shows there is no universally predictive correlation between DLVO energies and flocculation parameters. Some OM has the negligible influences whereas others exert non-DLVO interactions such as repulsive hydration and steric repulsion. Further understanding of the physical-chemical properties of OM is needed in order to predict the flocculation behaviors. (Abstract ID 9387)

IMAGING FLOWCYBOT DASHBOARD: WEB-BASED SUMMARIZATION, BROWSING, AND ACCESS TO NEAR-REALTIME PHYTOPLANKTON IMAGERY

 Imaging FlowCytobot is an automated flow cytometer that continuously samples seawater and provides near-real-time photometric and imaging observations of marine phytoplankton. IFCB has been deployed at the Martha’s Vineyard Coastal Observatory for over six years and has collected over 500 million images with associated fluorescence and scattering data.
Accessing and exploring this large time-series dataset has been difficult because FCB data is in non-standard formats and was only accessible within the research developer’s laboratory. As part of an Informatics Bridging Team effort pairing science users with informaticists, we have developed an interactive, web-based interface for displaying and browsing visual summaries of "live" FCB data. The interface is backed by RESTful web services providing FCB data in its native formats as well as multiple standard representations (PDF, XML, JSON, and CSV). The services provide FCB data with persistent, citable URLs for easy sharing and distribution, an approach we expect will be broadly applicable to other instrument platforms and sensor networks. TESTING THE BIOGEOCHEMICAL IMPACTS OF UPPER TROPHIC LEVELS WITH A STRUCTURALLY EFFICIENT GLOBAL MODEL.

Marine ecosystems are exceedingly complex, involving thousands of species of phytoplankton, zooplankton and nekton, all subject to the turbulent whirls of the chaotic physical environment. Parsing this complexity into comprehensible processes is difficult, and mechanistic plankton ecology has tended to focus on primary producers - visible by satellite - as the primary drivers of ocean biogeochemistry, with remineralizing organisms enslaved to variability in the primary producers. However, metazoans are also sensitive to environmental parameters, such as light, temperature and oxygen concentrations. As efficient metabolizers, these organisms can influence the distribution of remineralization, thereby altering the availability of nutrients and causing a feedback on phytoplankton. In order to test this, we introduce upper trophic levels as simple parameterizations in a structurally-efficient biogeochemical model, BLEN. We then isolate the effects of individual behavioral patterns, such as daily vertical migration, particle dynamics, and sensitivity to low oxygen concentrations. (Abstract ID 12568)

MINDING THE GAP: AMPLIFYING THE VOICE OF SCIENCE IN THE WIDER WORLD

Fundamental change in science is often the result of unexpected connections. Across disciplines and institutions, these connections often come about as a result of creative thinking about who to have in the room to tackle questions that are particularly timely or broad in scope. The Communication Partnership for Science and the Sea (COMPASS) helps ocean scientists connect themselves and their science to the wider world. We do this, in part, by ensuring that the latest science informs, frames, and catalyzes ocean policy discussions. For cases in which the science exists, we facilitate fitting the pieces together into a cohesive whole through synthesis and seed new collaborations. In other cases, we catalyze new science through scholarly workshops and working groups. We also create and capitalize on opportunities to connect scientists to decision makers through briefings, meetings, and other venues. These connections often feed back to generate additional ideas to advance the science. I will provide examples of each of these activities to illustrate how the resulting dialogue has built community, advanced the science, and informed policy. (Abstract ID 12468)

INFLUENCE OF WATER MASSES ON THE DISTRIBUTION AND ABUNDANCE OF SEABIRDS IN THE NORTHEASTERN CHUKCHI SEA

We examined relationships between oceanography and the distribution and abundance of seabirds in the northeastern Chukchi Sea in 2008–2010 as part of an interdisciplinary ecological study (Chukchi Sea Environmental Studies Program; funded by ConocoPhillips, Shell, and Statoil). We sampled 3 study areas located ~110–180 km offshore and known as Klondike, Burger, and Statoil. The total density of seabirds was considerably higher in 2009 than in 2008 and 2010 and generally was higher in Klondike than in Burger in 2008 and 2009; however, densities did not differ significantly among Klondike, Burger, and Statoil in 2010. Species-composition varied among study areas, seasons, and years, and the numerical dominance of alcid species in all study areas combined increased from 2008 to 2010. The distribution of seabirds may be influenced by advective processes that transport oceanic water from the Bering Sea to the Chukchi Sea. This transport differed among years and resulted in a broader northeastward intrusion of Bering Sea Water, higher abundance of oceanic zooplankton, and greater abundance of planktonivorous seabirds in 2009 than in 2008 or 2010. NONHYDROSTATIC HINDCASTS OF NONLINEAR INTERNAL WAVES IN THE LUZON STRAITS AND NORTHERN SOUTH CHINA SEA – TIDES AND THE KUROSHIO

Complex, large amplitude, Nonlinear Internal Waves (NLIWs) are generated in the Luzon straits by tides, by the Kuroshio and by their interactions with the bathymetry. These waves interact with each other and the topography to form highly energetic packets of NLIWs that propagate across the South China Sea. Nonhydrostatic hindcasts have been conducted at 500 m resolution in the Luzon Straits (18.5N – 21N, 119E – 124E). These hindcasts covered the period of the Internal Waves in Straits Experiment pilot cruise from August 1 to September 11, 2010. NLIWs originate from several sources around the Batan and Bahayan Islands. They interact to form a complex, energetic wave field which forms into NLIW packets that propagate westward. The Kuroshio significantly influences the flow in the Luzon straits. The results are in good agreement with moored measurements and remote sensing. These hindcasts were forced using data from hydrostatic hindcasts of the northern South China Sea (17N – 23.5N, 116E – 125E) at 2 km resolution. The hydrostatic hindcasts were initialized and forced using archived forecast fields from the global NCOM and the OSU tidal database. (Abstract ID 11437)

GRAIN SIZE AND MORPHOLOGICAL VARIABILITY

Grain size on beaches is often assumed to be uniform to reduce complexity in modeling studies and because measuring grain size is tedious and time consuming. Rubin (2004) introduced a technique for measuring grain size using auto-correlation of digital images. We used a similar technique for surveying grain size on beaches during two experiments in TrueVer90, spatial survey. Surface grain size were completed every few days over a large (~500x500m) intertidal area. Results indicate that grain size varies spatially with the morphology of beach features (e.g., rip channels and shoals) and changes with the dynamics of that morphology. The REX09 experiment focused on twice-daily sampling of two cross shore lines to examine temporal grain size variability of the intertidal beach. It was found that very coarse sediments are associated with the energetic shore break and swash on the steep foreshore. And that this pattern moves and changes with tide level, wave energy, and morphodynamics. These data being used to examine the relationship between morphological, sedimentological and hydrodynamic variability using Xbeach, a model for waves, currents, transport and morphodynamics. MEAN FLOWS AND WAVES IN BETA-PLANE TURBULENCE

The behavior of a strongly nonlinear system featuring inverse energy cascade and Rosby waves can be characterized in terms of a zonostrophic index (ZI) which measures the width of the zonostrophic inertial range. The latter is a part of the Kolmogorov energy transfer range where, due to the beta-effect, the anisotropy is strong. When ZI > 2.5, a flow is dominated by a system of strong, stable, long-lived zonal jets with a steep zonal spectrum. This regime is classified as zonostrophic turbulence. Its existence has been confirmed by the data collected during the recent fylyer near Jupiter of the Cassini space station. For 1 < ZI < 2, the flow is anisotropic but zonal jets are unstable and not well pronounced. This regime is typical of the ocean where ZI is only about 1.7 or less. Our simulations demonstrate that large-scale Rosby waves, energized by the inverse cascade, generate secondary, nonlinear, non-dispersive waves termed zonons. Zonons survive in a flow long after the forcing is switched off. Further analysis indicates that zonons are maintained and guided by the meridional shear of the zonal velocity, i.e., they reveal the attributes of the Rosby solitary waves. Zonons are the medium that facilitates the energy exchange between zonal flows and eddies by morphing them into a symbiotic relationship. These results shed new light upon the mean flow – eddy dynamics in beta-plane turbulence. (Abstract ID 12752)

MODULATION OF ATMOSPHERIC RESPONSE TO NORTH PACIFIC SST FROM GLOBAL WARMING: A STATISTICAL ASSESSMENT

The modulation of ocean-to-atmosphere feedback over the North Pacific in early winter from global warming is investigated based on observational data and multiple climate model simulations. It is found that global warming can significantly enhance the ocean-to-atmosphere feedback over the North Pacific, characterized by a robust warm ridge pattern. This enhancement is likely associated with the intensification of storm tracks in a warm climate. (Abstract ID 9367)
Eddy characteristics in the northeastern South China Sea are studied using the AVISO merged Sea Level Anomaly data from October 1992 to December 2010. Clustered in three Eddy-active periods, the northwest South China Sea is divided into three Eddy Centers, EC1-3, there were more anti-cyclonic eddies (ACEs) than cyclonic eddies (CEs). EC1 is situated west of Xisha Islands, with EC2 and EC3 north and northeast of Xisha, respectively. The occurrence of ACEs was highest in summer and lowest in winter; whereas the occurrence of CEs was higher in spring and fall. Most of the ACEs found in EC1 in the summer were generated southeast of EC1 in the spring, while most of the CEs found in EC1 in the fall were generated locally. On the other hand, most eddies found in EC2 and EC3 propagated to the areas from east. Eddy generation and propagation are further investigated in relation to the general circulation, wind stress patterns, and topography in the northwestern South China Sea. (Abstract ID 9750)

THE FORMATION, PATHWAY AND DESTINATION OF THE NORTH PACIFIC SUBDUCTION WATER IDENTIFIED BY A SIMULATED PASSIVE TRACER

The formation, pathway and destination of the North Pacific subduction water are investigated by using a simulated passive tracer, based on oceanic transports. The subduction water then participate in the subtropical gyre of north Pacific. About 30% of the subducted water up to the local mixed layer in early 2-3 years, and more and more subducts along the pathway of the Southern Ocean gyre is least efficient. A shallow mixed layer in low-NAO conditions is observed to initiate an earlier spring bloom in all three gyres. (Abstract ID 12014)

HICO ON-ORBIT CALIBRATION AND DATA CORRECTION

The HICO instrument (Hyperspectral Imager for the Coastal Ocean) is an imaging spectrometer presently onboard the International Space Station. This instrument does not carry any onboard optical radiometric calibration sensors. We have developed vicarious calibration techniques that have been used in converting the HICO L1A digital numbers to the L1B radiances. Spectrum-matching techniques are used to refine the wavelength and spectral resolution calibrations. Radiometric calibrations are made through inter-satellite data comparisons, mainly between HICO data and the radiometrically calibrated EOS/MODIS data. (Abstract ID 11662)

COMPARISON OF DECADAL CHANGES IN THE CARBON SINK AND POTENTIAL RESPONSES TO CLIMATE CHANGE IN THE WESTERN ARCTIC OCEAN AND THE SOUTHERN OCEAN

Model results show that the Southern Ocean (SO) carbon sink has weakened with global climate change. Our results out 3 years of observation, however, show that this is only partly true. Overall, the pCO2 in surface sea water increased faster than it increased in the air and there was ocean acidification. There were, however, seasonal differences, such that the above was the case in December, but not in January. The difference in pCO2 between air and the surface sea water (PpCO2) decreased dramatically from 1999 to 2007 in December, but not in January. The difference in the ΔpCO2 change between December and January suggests that the biological pump in the SO might have been enhanced under climate change. This is a potential feedback of the SO to climate change: The Arctic carbon sink increased between 1999 and 2010, as sea ice cover decreased. Increased ice melt in summer is projected to occur in the future with increasing speed. The increased CO2 uptake by the Arctic Ocean slopes and basins, thus, may provide a negative feedback mechanism to reduce atmospheric CO2 and thus the rate of global warming. This CO2 sink may gradually weaken, although it will remain higher than today. Furthermore, increased warming and ice-melt will also promote permafrost thawing in the Arctic landmass and thus increase river inputs of DIC and organic carbon, which will likely be recycled as CO2, further reducing the capacity of the Arctic Ocean to absorb atmospheric CO2. SEABORNE HYPERSPECTRAL REMOTE SENSING: AUTOMATED SUNGLINT FLAGGING AND FOREL-ULF CLASSIFICATION

Quality control of remote sensing measurements plays a vital role in the accurate determination of remote sensing reflectance (Rrs) or ocean color products, and the accurate estimation of optically active water constituents. We present a state-of-the-art setup for automated sunglint flagging and unmanne seahorse hyperspectral optical measurements. Simultaneous to optical measurements a dual-camera system was used to capture sun and sky images supporting the identification of sunglint in the radiometer field of view. Quality control was applied at first using three flags based on meteorological conditions, to select non-evaluable incoming solar irradiance. Finally a novel sunglint flag was applied using computed water
leaving radiance or R_RS, derived from automated image analysis. The remaining unmasked R_RS spectra were transformed into discrete values based on the FoulÉ-Index (FUI) simplifying the optical comparison of water bodies. This quality control method as well as FUA scale can be adapted to automatically generate high quality data useful in the validation of satellite R_RS, optical classification of water bodies, and eventual estimation of optically active water constituents as an element of ocean observatories. SPATIAL VARIATION IN MICROBIAL COMMUNITY FUNCTIONAL GROUP COMPOSITION IN SURFACE WATER AND SEDIMENTS IN DORCHESTER BAY OF BOSTON HARBOR

Boston Harbor restoration has been ongoing for 30 years and has improved water quality. The goal of this study was to compare surface water and sediment microbial communities from the mouth of the Neponset outfall at 3 locations in Dorchester Bay. We measured physico-chemical parameters and characterized the microbial communities of surface water and bottom water/sediments at the mouth of the Neponset River (NEP), Thompson Island (TI), and Spectacle Island (SI) in summer 2011. Surface and bottom water samples were measured for physico-chemical properties and analyzed using Principal Components Analysis (PCA) and sediment microbial communities will be analyzed using Fatty Acid Methyl Esters (FAMES) and statistically analyzed using PCA. PCA Axes 1 and 2 explained 100% of the variability in surface and sediment water physico-chemical parameters. Axis 1 separated TI from NEP and SI samples, and while Axis 2 separated all 3 sampling stations with TI being intermediate to NEP and SI. Based on PCA results, we expect microbial communities to be similar among the sediment samples and different among the surface water samples. (Abstract ID 9624)

THE BROAD-SPECTRUM BENEFITS OF RESEARCH PARTNERSHIPS BETWEEN TEACHERS AND MARINE SCIENTISTS

Fostering partnerships between scientists and pre-college classrooms is a win-win scenario for both sides: Developing experiences in authentic research not only impacts the teacher and her students, but also has the potential to change thinking in the community. Co-authors Yager and Garay originally met through the Polar Trex program. Now in their 4th year of working together, the partnership has grown from co-authoring a classroom activity to developing a tri-state global ocean project that connects coastal students in Texas, Georgia, and Alabama! Partnerships like this expand the teacher/student's knowledge base and gives depth to learning by bridging the gap between real-time research and classroom studies. The direct, personal relationship allows students to see scientists as real people facing real challenges in their work. And, brings attention to different career disciplines and new technologies. For teachers, scientists provide background for new concepts and technical knowledge of equipment and procedures, as well as a stimulating exchange of ideas that meets STEM objectives. The scientist benefits from the educational outreach developed from their work, giving exposure to timely scientific topics. (Abstract ID 12038)

CLIMATICALLY ACTIVE GASES IN THE EASTERN BOUNDARY UPWELLING AND OXYGEN MINIMUM ZONE (OMZ) SYSTEMS

The EBUS (Eastern Boundary Upwelling Systems) and OMZs (Oxygen Minimum Zone) contribute very significantly to the gas exchange between the ocean and the atmosphere, notably with respect to the greenhouse gases (hereafter GHG). From in-situ ocean measurements, the uncertainty of the net global oceans-atmosphere CO2 fluxes is between 20% and 30%, and could be much higher in the EBUS-OMZ. Off Peru, very few in-situ data are available presently, which justifies alternative approaches for assessing these fluxes. GHG air-sea fluxes determination can be inferred from inverse modeling applied to Vertical Column Densities (VCDs) from GOSAT, using state of the art modeling, at low spatial resolution. For accurately linking sources of GHGs to EBUS and OMZs, the resolution of the source regions needs to be increased. This task develops on new non-linear and multiscale processing methods for complex signals to infer a higher spatial resolution mapping of the fluxes and the associated sinks and sources between the atmosphere and the ocean. The use of coupled satellite data (e.g. SST and/or Ocean colour) that carry turbulence information associated to ocean dynamics is taken into account at unprecedented detail level to incorporate turbulence effects in the evaluation of the air-sea fluxes. We will present a framework as described above for determining sources and sinks of GHG from satellite remote sensing with the Peru OMZ as a test bed. (Abstract ID 11997)

STRUCTURE OF SMALL-SCALE TURBULENCES AT THE FREE AIR-WATER INTERFACE

In this contribution we will present a new approach for analyzing interfacial shear induced turbulence at the free air-water interface. We use an infrared imager sensitive in the spectral range form 3-5 µm for visualizing the water sided turbulence from passive thermography. Due to a heat flux present at the interface, a temperature difference exists between the skin layer and the water bulk below the diffusive sub-layer. Turbulence disrupts the boundary layer, the temperature footprint of which can be seen in the images. Due to the shear at the interface, turbulences are not isotropic but exhibit elongated streaks in wind direction. We will present a novel image processing based approach for classifying and segmenting the streaks. From these segmentation, statistical distributions of streak spacings can be analyzed. As expected, a trend towards smaller streak spacings with increasing friction velocity is evident. Surprisingly, above a certain threshold friction velocity, streak spacings appear to remain constant. Besides small-scale structures, we also examine larger scale coherent structures, which can be associated with Langmuir circulations. We relate our findings to the Langmuir number for a first indication of the production processes of these structures. Results from laboratory and field measurements will be presented. (Abstract ID 10147)

RESPONSES OF MARINE N, FIXATION TO INTERACTIVE GLOBAL CHANGE EFFECTS. TRICHODESMIUM AND CROCOSPHAERA COMPARED AND CONTRASTED

Within the past five years, new attention has focused on effects of global change on marine N2 fixation. In addition to Trichodesmium, unicellular N fixers like Crocosphaera watsonii are now recognized as major components of the diazotrophic community. Several recent studies suggest that elevated pCO2 has a positive effect on N2 fixation rates by both of these groups of N2 fixers. These cyanobacteria, and that light interacts with pCO2 in controlling cellular retention of N2 fixation. We will present a framework as described above for determining sources of GHG from satellite remote sensing with the Peru OMZ as a test bed. (Abstract ID 11907)

EFFECTS: 2011 MISSISSIPPI RIVER FLOOD ON CO2 FLUXES IN THE LOUISIANA COASTAL ZONE: LINKAGES WITH RIVERINE DOM INPUTS

The flood of the Mississippi River basin and the opening of the Morganza spillway in the spring of 2011 provided a unique opportunity to study CO2 evasion from the coastal region when there is a large injection of terrestrial-derived DOC. As worldwide floods become more
frequent and severe, one possible effect is the accelerated release of terrestrial organic matter into the coastal zone. The liability of this terrestrial-derived DOC will determine how quickly it may be oxidized to CO₂ and released to the atmosphere. Characterizing the dissolved inorganic carbon and understanding the sea to air fluxes of CO₂ before, during and after the event allow us to examine the implications of such events for climate change and carbon sequestration. Here, we present the results of measurements of Dissolved Inorganic Carbon (DIC), Total Alkalinity (TA), Dissolved Organic Carbon (DOC), and pCO₂ levels from the inner shelf to the tidal freshwater portion of the Achafalaya River estuary. Discrete TA and DIC samples were collected and pCO₂ was measured continuously during pre-flood, flood and post-flood cruises. (Abstract ID 9931)

REMOTE SENSING OVERVIEW OF BP OIL DISCHARGE FROM SATELLITE SAR DATA.

Satellite remote sensing played a crucial role for monitoring BP's oil spill in the Gulf of Mexico (GOM). Oil discharged from the wellhead started to be detected by satellites on 23 April 2010. and oil slicks associated to this event were observed until 15 July. To map the extent, location, and evolution of the spill, we used a previously developed image processing algorithm called TCNNA which processes satellite Synthetic Aperture Radar (SAR) data. Monitoring of this event by processing 37 SAR images collected during the event allowed us to detect rafts of oil in the coastal zone as they separate from the much larger main spill that is centered around the BP well site. These oil rafts were detected moving at a rate of 15 miles per day and making landfall progressively as winds and tides push them along the coast. In deeper waters, drifting oil moved up to 45 miles per day and as far as 300 km away from the well source. This happened when, oil was reached by the loop current which carried the floating layer of oil southeast from the wellhead. As shown in Figure 1, repeated observations of floating oil increased with proximity to the oil source. By normalizing oil detections by the frequency that each area was sampled, we estimate that oil covered a mean daily area of 10750 km². In total, oil covered a cumulative extent of 119,600 km² of the GOM surface waters. (Abstract ID 11622)

DISTRIEBUTION AND ND ISOTOPES ALONG THE BONUS GOODHOPE SECTION IN THE SOUTHEAST ATLANTIC OCEAN

Dissolved and particulate concentrations of Rare Earth Elements (REEs) and dissolved neodymium isotopic composition (εNd) have been measured in seawater along the Bonus GoodHope (GEOTRACES/PlFA) section in the Atlantic sector of the Southern Ocean. Dissolved REE concentrations increase with depth (e.g., from 11 to 33 pmol·kg⁻¹ for Nd) and their normalized patterns evidence a clear enrichment of HREEs relative to LREEs, together with a pronounced negative Ce anomaly at all the stations (0.06-0.14). Overall, εNd range mainly from −17 to −14 for seawater, −15 to −14 for DIC samples and −17 to −14 for pCO₂ levels. The εNd values for DIC samples were consistently lower than those for pCO₂, which indicate that dissolution of continental crust-like PAAS-normalized patterns of particulate REEs, and remarkably negative εNd values (−17 to −15) for seawater suggest a strong contribution from reworked continental crust. We proposed the existence of a specific mutualism for these processes which would be important for both dissolved and particulate phases, suggesting equilibrium between them or that the particles are authigenic. A preliminary mixing model, assuming conservative εNd and salinity, evidences the dilution of NADW at southern latitudes: i.e. the εNd of modified NADW seems to be primarily controlled by water mass mixing. (Abstract ID 9693)

THE ROLE OF PHOTOREACTIVE SIDEROPHORES IN ALGAE-BACTERIA INTERACTIONS IN SITU

Certain phytoplankton may have a symbiotic association with specific bacterial species driven by a mutualistic relationship of photosynthetically fixed organic carbon and heterotrophic remineralization of limiting nutrients. We proposed the existence of a specific mutualism between vibrioferrin (VF) producing Marinobacter and members of the dinoflagellate and coccolithophoridal algal lineages. This photosynthetically active siderophore VF provides an enhanced supply of Fe(III) to the algae and in return the bacteria would benefit from the release of photosynthate supporting their growth. To provide evidence for this bacterial-algal association we analyzed bacterial community structures with emphasis on the in situ abundance and succession of Marinobacter species inside and outside phytoplankton blooms. Using in situ fluorescence hybridization (FISH) and Marinobacter specific probes we could determine the correlation of certain Marinobacter species with dinoflagellate blooms. Furthermore we detected vibrioferrin biosynthetic genes using quantitative Real-Time PCR (qPCR) and analyzed the importance and abundance of other marine photoreactive siderophores like aerobactin and petrobactin. With this we hope to estimate the potential role of photoreactive siderophores in oceanic iron cycling and their contribution to bacteria-algal mutualism in correlation to phytoplankton blooms. THIN SURFACE LAYER TRANSFER OF CHROMOPHORIC DISSOLVED ORGANIC MATTER (CDOM) IN ESTUARIES

Observations and modeling of transport processes in estuaries frequently under resolve the upper 50 cm of the water column. Instrument packages developed at UMass have allow us to effectively examine this region. We have frequently found low salinity water, and associated high CDOM concentrations, to be confined to a very thin surface layer, especially following rain events. While this layer may represent a small portion of the system and only occurs episodically, it may account for a significant loss of nutrients from the transport of dissolved constituents from land to the coastal ocean. We will present data from towed vehicles as well as from 5 buoys which have been deployed from near the head of the Neponset River Estuary to the mouth of Boston Harbor. The buoys support salinity and CDOM sensors at approximately 30 cm water depth. Output from a high resolution finite difference model will be compared with the field data and used to assess the importance of the thin surface layer for CDOM transport and in determining the residence time of fresh water in the harbor. INCERTAINCE UNDER-REPRESENTED HIGH SCHOOL STUDENTS INCREASED AWARENESS AND KNOWLEDGE RESULTS OF LIBERTY SCIENCE CENTER'S APPROACH

From December 2010 through June 2011, Liberty Science Center offered a two-day Ocean Science program to 208 high-school students and their teachers from 10 Newark, NJ, high schools. Our goals were to show students the interdisciplinary nature of science, increase their ocean literacy, enhance their ability to interpret and manipulate data, and increase their understanding of how ocean scientists do their work. The program included four data-oriented lessons developed under COSEE-NOW using ocean observing systems to teach physical and chemical oceanography and tied to that other lessons emphasizing the carbon pump and associated organisms. To evaluate the program, students completed a survey at the beginning and end of the two days (pre-post test design). Teachers completed a post-program survey rating program quality, alignment to curriculum and appropriateness for students. Matched pre-post student survey results showed increases in awareness of and knowledge about the physical and chemical characteristics of the ocean, the ocean's impact on their daily lives and scientists' ability to conduct research remotely. The program was well received, and Newark schools requested additional sessions in the coming year. (Abstract ID 11247)

UNTANGLING THE TIME-DEPENDENT MIXTURE OF FORCES GENERATING TURBULENCE IN SHALLOW SHELF SEAS

Turbulence within the water column of shallow shelf seas is produced by a mixture of forcings: wind stress, wave-induced Langmuir vortex force, and unstable buoyancy flux acting at the top, bottom stress associated with dominantly tidal flows at the bottom. In general, this mixture of forcings is highly time-dependent, varying on tidal, diurnal, storm, and seasonal scales. Because important characteristics of turbulence (vertical velocity variance, vertical fluxes and net horizontal transport of sediment and bioactive material) vary dramatically with forcing mechanism, it is of interest to be able to identify periods when a single forcing mechanism dominates. Using as a metric direct observations of turbulent vertical velocity variance taken over extended periods of time at two sites differing in water depth and tidal amplitude, I will present methods of determining when a single forcing mechanism dominates, either in time and or with depth in the water column. TRACER MODELING WITH THE HYBRID COORDINATES OCEAN MODEL (HYCOM).

A series of tracer simulations are being conducted at NCEP/NWS for a variety of applications, from dispersion of radionuclide contaminants motivated by the Japanese nuclear accident near Fukushima, to nutrient estimations. The tracer capabilities of HYCOM are used, in regional domains, to test the ability to forecast fields from the 1/12° HYCOM (RTOPs-Global) model output. In this study, results are presented from the soon-to-be first operational ocean dispersion model at NCEP/NWS, addressing the Fukushima-Daiichi nuclear accident, March 11, 2011. Similar tracer simulations are intended for applications like oil spills, radionuclides, and for ecosystem modeling. (Abstract ID 9531)

PYRITE NAPANPITICLES FROM HYDROTHERMAL VENTS ARE A POTENTIAL SOURCE OF IRON TO THE OCEAN

Recent calculations demonstrate that iron emitted from hydrothermal vents has an impact on the iron budget of the world ocean, and the pathways by which iron is transported from the immediate vent region to the larger ocean basin are being explored. We show TEM and SEM images of pyrite nanoparticles (collected from black smokers at Lau Basin in May 2009) as small as 4 nm, which are aggregated into larger ‘nano-frames’ of 50-300 nm in size. The mass balance analysis of vent samples collected on the same cruise demonstrated that up to 10% of the total iron emitted from black smokers was present as pyrite nanoparticles smaller than 0.2 µm. Kinetic experiments of synthesized pyrite nanoparticles suggest that these nanoparticles persist in oxygenated seawater solution and do not oxidize readily. The pyrite nanoparticles appear to behave as dissolved entities as the oxidation rate law shows first order dependence in pyrite nanoparticle concentration. We suggest these pyrite nanoparticles are a potential source of iron to the larger ocean. (Abstract ID 10428)

BIOFILMS AND SIZE SORTING OF INTERTIDAL SEDIMENT DURING EROSION

Biofilms found at the sediment surface are known to limit sediment resuspension. It is thought that biofilms preferentially retain fine particles, but this hypothesis remains to be tested. The goal of this study was therefore to investigate size-specific grain retention by biofilms. Sediment cores were collected from an intertidal flat and eroded with a Gust microcosm erosion chamber at various shear stresses (0.08-0.60 Pa). Half of the cores were eroded without prior treatment, while sodium hypochlorite was added to the other cores to destroy biofilms. Disaggregated inorganic grain size (D10%) distributions were obtained for the resuspended sediment and each treated core was compared to its corresponding untreated core. At intermediate shear stresses, biofilms were found to preferentially retain large grains. (Abstract ID 9918)

FEEDBACKS BETWEEN HIGH PHYTOPLANKTON BIOMASS AND THE IN SITU HEAT BUDGET

For the Long Term Ecological Research project, we have measured the inherent (IOP) and apparent (AOP) optical properties along the West Antarctic Peninsula. This region is characterized by large coastal diatom blooms that can be >30 mg chlorophyll /m^3. Such high phytoplankton concentrations suggest there is a potentially significant feedback between the algal biomass and the radiant heat budget in coastal waters. Using in situ measurements, optical closure was achieved between the IOPs and AOPs via HydroLight. This closure provided confidence in the in situ measurements. The 1% light levels ranged from 5-50 meters depth over the observed 10-fold changes of chlorophyll, suggesting that most of the radiant heat is trapped in the upper few meters of the water column. High surface temperatures (>4 degrees C) are observed in nearshore waters often in the high chlorophyll water. Using measured surface light and in situ optics, the calculated heating rates corroborate ship temperature measurements. These results emphasize the need to accurately model optical variability and feedbacks in Antarctic coastal waters to accurately resolve the surface radiant heat budget. (Abstract ID 10622)

THE INFLUENCE OF NONLINEAR MESOSCALE EDDIES ON OCEANIC CHLOROPHYLL

High-resolution sea-surface height (SSH) fields constructed from altimeter data have revealed the ubiquity of nonlinear, coherent eddies with mesoscale radii of ~100 km throughout the World Ocean. We investigate the influence of these eddies on oceanic biology from 10 years of upper-ocean chlorophyll (CHL) estimates collocated to the eddies inferred from the SSH fields. The observed westward propagation of CHL and SSH previously attributed to linear Rossby waves is shown to be due to nonlinear eddies that were not resolvable in the SSH fields analyzed in past studies. At temporal scales of weeks to monthly and spatial scales greater than 100 km, the dominant mechanism is shown to be eddy-induced horizontal stirring of the ambient CHL field.

While the horizontal advection of CHL by the rotational velocities of eddies dominates the statistics of CHL variability globally, trapping of CHL within the cores of highly nonlinear eddies is found to be important in anticyclonic eddies in specific regions. From collocation of scatterometer wind fields to the eddies, it is shown that the interaction between the anticyclonic eddy surface currents and the background wind field results in a sustained cyclonic wind stress curl at the cores of anticyclonic eddies. This eddy-induced Ekman pumping injects nutrients into the euphotic zone and thus plays a critically important role in sustaining the ecosystems trapped within the nonlinear cores of anticyclonic eddies. ON THE USE OF SUB-MESOSCALE TRACER INFORMATION AND MESOSCALE ALTIMETRIC FIELD FOR THE CONTROL OF OCEAN CIRCULATIONS

Ocean mesoscale eddies are essential components of the ocean circulation which is currently best observed by altimetric satellites. In addition, high resolution sensors of geo-chemical tracers such as Sea Surface Temperature or Ocean Color reveal even smaller structures at the sub-mesoscale, which are not detected by altimetric satellites. These two types of scales (mesoscale/sub-mesoscale) and their related products (altimetric field/tracer image) provide a representation of the same physical/bio-geochemical reality of the ocean.

In this study, the potential benefit of these two types of complementary observations is explored, with the aim of refining the estimation of the ocean circulation. More specifically, the Finite-Size Lyapunov Exponents (FSEs) are used to extract filaments from the turbulent mesoscale velocity field. Comparing the FSLEs and the tracer patterns, it is shown that image information can be inverted to retrieve the corresponding velocity.

This process yields an improved description of mesoscale currents from altimetry as well as the knowledge of vertical motions which are essential to biogeochemical modeling. The perspectives offered by this approach, combining altimetric mesoscale observations and sub-mesoscale tracer images, will conclude the presentation. (Abstract ID 9685)
Gay, P., Naval Oceanographic Office, Stennis Space Center, USA, peter.gay@navy.mil

The hydrographic structure and flow over the continental shelf between Chesapeake Bay and Cape Hatteras is subject to a number of upstream influences. A short cruise to examine the distribution of fish schools in this region and their relation to known hydrographic features (Cold Pool and the shelfbreak front) was conducted from September 9-15, 2011 on the R/V HATTERAS: IMPACT FROM RECENT FLOODING

AN EVALUATION OF THE PERFORMANCE OF SWAN WAVE PREDICTIONS USING OFFSHORE U.S. BUOYS

In order to evaluate the wave predictions of the U.S. Naval Oceanographic Office (NAVOCEANO), we have set up models using NAVOCEANO’s implementation of the Deltas Swan wave prediction model to generate wave spectra for nine locations around the United States that are coincident with wave buoys. We evaluate the model skill by comparison with the buoy data, comparing significant wave height, peak period, and mean wave direction. A year of twice-daily SWAN model runs with hourly predictions is evaluated. In addition to comparing the entire time-series with buoy observations, the data are stratified by season, as well as local wind strength and direction, to determine the conditions for optimal (and worst) model performance. The difference in geography of the locations (complexity of the adjacent coast and exposure to remotely-generated swell) is also considered. The results can be applied to estimate how well the model will perform in conditions analogous to those considered in this study. (Abstract ID 10288)

UPPER OCEAN TURBULENCE RESULTING FROM THE INTERACTION OF AN INTERNAL WAVE BEAM WITH A PYCNOCLINE

Numerical simulations are performed to investigate the interaction of an internal wave beam with an upper ocean pycnocline. The focus is on turbulence in the pycnocline that may result owing to nonlinearities during transmission and reflection of the internal wave field. Linear inviscid solutions based on ray theory are also used to provide guidance on the reflection dynamics of the internal wave beam. At low values of the Froude number, $Fr$, linear theory and numerics show excellent agreement. At moderate values of $Fr$, solitary wave like features form at the interface. Furthermore, higher harmonics in the reflected wave response, affected by multiple reflections by the turning points inside the pycnocline, are trapped. The simulations reveal the major role of convective instability in initiating turbulence during the tunnelling of the internal wave beam through the upper ocean pycnocline. The energetics and the phasing of internal wave energy conversion to upper layer turbulence will be quantified. (Abstract ID 10810)

ISOLATION AND CHARACTERIZATION OF BACTERIALSAMPLES FROM ASSATEAGUE ISLAND MARYLAND

Methods for the classification and identification of bacterial organisms are constantly changing due to advances in the knowledge of molecular biology tools available for such processes. Methods used today can range from simple staining techniques that reveal morphology to more complex molecular techniques such as metagenomics that allow characterization of unculturable microorganisms. In this study, soil and water samples from Assateague Island Maryland were collected and used to inoculate Salt water and Nutrient agar media for microbial isolation and characterization. Gram staining confirmed the presence of Gram positive and Gram negative bacteria. Biochemical characterization with TSI and MacConkey agar media confirmed acid production but no lactose fermentation. We performed molecular characterization on three bacteria isolates using universal 16s rDNA primers to identify the family and genus of the organisms but unsuccessful. The three isolates included bioluminescent bacteria, an antibiotic producing bacteria and lawn forming bacteria. Future work will attempt to repeat the molecular characterization approach. DISTRIBUTION OF THE HOLOCENE-AGE PEARL RIVER-DERIVED SEDIMENT ON THE DELTA AND CONTINENTAL SHELF

High-resolution Chirp profiling and coring reveals an elongated (~ 400 km) Holocene Pearl River- derived mud area (thickness ~ 30 m) extending from the Pearl River delta plain southwestward off the Guangdong coast to the Leizhou Peninsula. On the continental shelf off the west Guangdong Province, the mud is deposited in water depth shallower than 50 m, while to the southeast of the Pearl River estuary, the mud area can extend to the ~ 120 m isobath. Through analyzing the terrigenous sedimentary sequences from other continental shelves of the Western Pacific marginal seas, we find the initiation of the mud area can be further divided into two stages: before the mid-Holocene sea-level highstand (MHSH), the distal mud was deposited between 11.2 and 9.8 cal ka BP when the sea-level rose slowly after the meltwater pulse (MWP) -1B. The proximal mud was deposited after 9.8 cal ka BP when the sea-level rose slowly after the MWP-1C. On the MHSH, clinoform developed on the continental shelf off the west Guangdong Province, extending ~ 150 km from the Pearl River estuary. (Abstract ID 9672)

A GLOBAL ESTIMATE OF OCEAN AGE AND TRANSIT TIMES INFERRED FROM RADIOCARBON OBSERVATIONS

A number of previous observational studies have found that the waters of the deep Pacific Ocean have an age, or elapsed time since contact with the surface, of 700 to 1,000 years. Numerical models suggest ages twice as old. Here we present an inverse framework to determine the mean age and its upper and lower bounds given GLODAP radiocarbon observations, and we show that the potential range of ages increases with the number of constituents or sources that are included in the analysis. The inversion requires decomposing the world ocean into source waters, here obtained using the Total Matrix Intercomparison method at up to 2 by 2 degree horizontal resolution with 11,113 surface sources. We find that the North Pacific at 2,500 meters depth can be no younger than 1,100 years old, which is older than some previous observational estimates. A best estimate of mean age is also presented using the mixing history along circulation pathways. Subject to the caveat that the estimate would benefit from further observations and that radiocarbon cannot rule out the presence of extremely old waters from exotic sources, the deep North Pacific waters are 1,200 to 1,500 years old, which is more in line with existing numerical model results. TRANSPORT VARIABILITY OF THE ACC AND TELECONNECTION WITH THE SOUTHERN ANNUAL MODE (SAM) SOUTH OF AFRICA

To study the Antarctic Circumpolar Current (ACC) volume transport several cruises have taken place. The results of these cruises show snapshots without information about the time variability. To investigate the time variability of the ACC the Alfred Wegener Institute operates an array of Pressure Inverted Echo Sounders (PIES) along a satellite altimeter ground track south of Africa. PIES monitor ocean bottom pressure and acoustic travel time across the water column. A Gravest Empirical Mode (GEM, Meinen and Watts 1998) was applied to determine the geostrophic transport between the PIES. These time series were used to compute a transfer function between satellite derived transport and geostrophic transport. Satellite altimetry offers the possibility to calculate ACC transport between 1992 and 2010. A mean transport of 115 Sv and a variability of 7 Sv were derived for the Topex/Poseidon, Jason 1 and Jason 2 time period. A wavelet analysis shows that the ACC transport highly correlates with the winter and spring SAM index, whereas a direct correlation on a monthly scale could not be shown. (Abstract ID 11016)
While evidence for impacts of ocean acidification on surface water ecosystems is accumulating, little is known on the timing and the amplitude of chemical changes in the deep-sea. In contrast to shallow water organisms, which are adapted to large changes in temperature and water chemistry, the deep-sea fauna has evolved under stable environmental conditions and might be highly vulnerable to small changes in seawater chemistry. We quantified the extent of changes in deepwater pH in 5 fully-coupled climate-carbon-cycle models in the North Atlantic under a “business-as-usual” emission scenario. All models project decreases in pH exceeding 0.2 units by the year 2100 regionally reaching down to 3000 m. Typical habitats of this depth range include hotspots of North Atlantic biodiversity. Reductions in pH beyond this threshold have been reported to be detrimental to deep-sea benthic organisms. Moreover, these pH reductions exceed the natural variability of pH in North Atlantic bottom waters. Chemical changes of this amplitude are much larger than any variability that organisms have experienced during at least the last 650,000 years. (Abstract ID 12458)

INTEGRATING RESEARCH AND EDUCATION FOR BROADER IMPACTS:

Community colleges are an important pathway for students intending to complete a baccalaureate degree, particularly for groups underrepresented in science. Students at these institutions have few opportunities to engage in research and even fewer opportunities in ocean sciences. To address this need, the NSF-funded Center for Ocean Sciences Education Excellence (COSEE) Pacific Partnerships developed an internship program for community college students. Promoting Research Investigation in the Marine Environment (PRIME) is an intensive, multi-site program that over the past four years has placed 31 interns with 25 scientist mentors for 8-10 week summer research experiences in Oregon, Washington, and Hawaii. Our evaluation demonstrates that the program is a successful, replicable, and rewarding model for engaging scientists in broader impacts activities, increasing ocean literacy, and broadening participation in science. PRIME scientist mentors value the program and in working with community students. Several mentors continued supporting students to work in their labs after the internship ended. PRIME provides valuable research experience for students that can further their careers. PRIME builds partnerships between scientists, community colleges and informal science education institutions. (Abstract ID 10730)
BENTHIC OSTRACODE ASSEMBLAGES IN THE BERING SEA FROM 1976 TO 2010

To further our understanding of recent climate and oceanographic changes affecting the Bering Sea ecosystem, we are analyzing living ostracode assemblages from the Northern Bering Sea collected during research cruises on the Polar Sea (2010), the Healy (2006, 2007, 2009), Alpha Helix (1990, 1994, 1999), Karluk (1978), and the Sea Sounder (1976, 1977, 1978). Many ostracode species have a geographic distribution limited by survival/reproductive temperatures, so they are useful monitors of climatic and oceanographic change. A total of 11 species were identified from 180 Bering Sea surface samples. Temporal patterns suggest the Bering Sea assemblage composition has responded to short-term temperature changes. For example, the abundance of Pseudopunctatilla, a predominantly Arctic species, decreased from 18-19% in the 1970s to 1% by 2009. This decrease coincided with changes in the PDO and higher Bering SSTs through the mid-2000s. In contrast, Pectocythere, a temperate genus, made up ~4% of the assemblage in 1990 but increased to 14% by 2006, as SSTs rose. Lower SSTs in the late 2000s may have caused this species’ decline to 2% in 2010. Our results support that recent ocean temperature changes in the Bering Sea region are affecting benthic ecosystems. However, because many factors influence biological responses, uncertainty about the impacts of climate change on marine ecosystems and interpretations remain. (Abstract ID 11574)

OCEAN-ICE SHELF INTERACTIONS IN THE EASTERN ROSS SEA

The narrow shelf between the Amundsen and Ross Seas shows nearly freezing and low salinity surface water carried westward by the Antarctic Slope and Coastal Currents. Around Cape Crocket the coastal flow turns north and subsurface waters offshore have direct access to the Ross Ice Shelf along the Little America Trough (LAT). Undetected in summer data are intrusions of warmer Circumpolar Deep Water available at the slope. To investigate the year-long transport along this path, and the ensuing ocean ice-shelf interactions in the eastern Ross Sea, an array of moored subsurface temperature, salinity and current recorders was deployed during February 2010-March 2011 near the outer and mid portions of the LAT. We will characterize currents and water mass properties revealed by these records and two short CTD transects spanning the moorings occupied during their recoveries on the CLIVAR Repeat Section cruise. Active ocean-ice interactions are indicated by intermediate meltwater outflow in early winter, preceded by relatively warm subsurface influences throughout the summer, and followed by a weakly stratified water column that persisted during the rest of the year. CANTON OCEAN EDDY EFFECTS BE PARAMETERIZED IN CLIMATE MODELS?

Eddy effects in the Antarctic Circumpolar Current are of leading order importance, where they oppose the meridional overturning of the mean flow. Results from control and 1% year increasing carbon dioxide runs of the CCSM using eddy-resolving resolution of 1/10 degree in the ocean and sea ice components will be compared to results using 1 degree resolution in these components. How well the eddy parameterization in the 1 degree runs performs will be evaluated by comparison with the 1/10 degree runs, where the mesoscale eddies are resolved. (Abstract ID 9308)

SPATIAL VARIABILITY OF DIURNAL WARMING FROM SATELLITE MEASUREMENTS OF SST

Diurnal warming events between 5 and 7 K, spatially coherent over large areas (~1000 km), are observed in independent satellite measurements of ocean surface temperature. A global study of these diurnal events show that the majority of the large events occurred in the extratropics. Given sufficient heating (from solar radiation), the location and magnitude of these events appears to be primarily determined by large-scale wind patterns. The amplitude of the measured diurnal heating scales inversely with the spatial resolution of the different sensors used in this study. Validation of diurnal warming using satellite data, must consider the spatial resolution of the sensor. These results indicate that predictions of peak diurnal warming using wind speeds with a 25 km spatial resolution available from satellite sensors and those with 50-100 km resolution from Numerical Weather Prediction models may have underestimated warming. Thus, the use of these winds in modeling diurnal effects will be limited in accuracy by both the temporal and spatial resolution of the wind fields. (Abstract ID 10427)
High temperature venting occurs in all oceans at all spreading rates and the ocean residence time for cycling through hydrothermal plumes is comparable to that for thermo-haline circulation. What impact, then, might high-temperature venting have on ocean biogeochemistry? I will discuss two threads of relevant research. First, recent Mid-Atlantic Ridge studies have determined export fluxes for heat, mass, and a range of trace elements and isotopes from a single vent-site to the ocean. While that study focused exclusively on high-temperature fluxes, it can serve as a template for future work. What is required next is an integrated study of diffuse and focused axial hydrothermal flow from a basal-hosted system at a medium- to fast-spreading ridge over the decadal timescale from one volcanic eruption to the next. Second, recent work has shown that hydrothermal systems may play a significant, previously overlooked role in exporting stabilized dissolved colloidal Fe to the deep ocean and that the fate of this essential micronutrient may be intimately coupled with the organic carbon cycle, even within the first few seconds following vent discharge from the seabed. Who knows what else might be revealed from a more thorough investigation of the fate of dissolved and particulate major and trace elements and their isotopes in a dispersing hydrothermal plume?

The next section of the US GEOTRACES program, provisionally scheduled for late 2013, will be well placed to address that. (Abstract ID 9065)
The role of non-breaking wind-generated surface waves in the turbulent mixing of the upper ocean has been mostly overlooked, but recent research suggests that the effect could be strong enough to significantly alter local climates, and introducing this effect into climate models could lead to improvements in seasonal climate prediction. Surface waves, particularly those on the ocean, are normally presumed to be irrotational and to have little or no interaction with near-surface turbulence giving rise to through-surface injection of turbulent kinetic energy and distortion of turbulence by the Stokes drift. However, no real waves are irrotational, and it has been known for at least half a century that they can generate turbulence; furthermore, the turbulence is unstable to the irrotational orbital motion of the waves which leads to growth of the turbulence. By modelling the turbulence generation in a large eddy simulation we have developed a parameterisation which we then introduced into an ocean mixing model. The results show that a decrease in surface temperature of around two degrees can occur quickly under large enough waves. (Abstract ID 9674)

TEST OF COMPOUND SPECIFIC STABLE ISOTOPE ANALYSIS FOR DETERMINING TROPHIC POSITION IN FRESHWATER ECOSYSTEMS

Compound specific stable isotope analysis (CSIA) of source and trophic amino acids is a novel technique for determining trophic position of organisms that has been employed over the past decade in marine and estuarine foodwebs. However, few studies have applied this approach in freshwater systems. To investigate the efficacy of this approach for use in floodplain rivers, controlled laboratory experiments were conducted using model organisms (Clamydomonas sp. as producer and Daphnia magna as consumer). The algae were maintained in continuous culture using defined media with ammonium chloride and calcium nitrate as nitrogen sources. Daphnia were maintained in continuous culture with the algae culture effluent serving as the Daphnia culture media. Algae were collected from the effluent and Daphnia were harvested after completion of two generations. Nitrogen salts, algae and Daphnia were analyzed for δ15N ratios. Amino acids were recovered from algae and Daphnia by acid hydrolysis and purification by ion exchange and their triﬂuoroacetyl/isopropanol ester derivatives formed. Trophic positions, calculated from whole-organism and amino acid CSIA δ15N ratios were compared to demonstrate the efficacy of the CSIA approach in freshwater systems. (Abstract ID 10611)

IDENTIFICATION OF THE TWO ACARTIA TONSA POPULATIONS LOCATED IN NARRAGANSETT BAY AND ANALYSIS OF THE BIOLOGICAL DIFFERENCES PRESENT BETWEEN THEM

Genetically distinct clades of the estuarine copepod, Acartia tonsa, have been identified. It is hypothesized that each may have specific habitat or culturing requirements. A. tonsa resting eggs were collected from Narragansett Bay, RI, sediment in early spring and hatched out at a series of increasing temperatures. These were raised in the laboratory and adult females fixed for DNA extraction and sequencing using the rRNA and small subunit rRNA genes. Two clades were identified from eggs hatched from the same sediment sample. These were present in approximately equal proportions and these proportions remained the same at the different hatching temperatures. Separate cultures of each clade were established and mating experiments were set up where unmated adults of the same and opposite clades were placed together. Eggs produced by females crossed with males of the opposite clade were not viable. These findings support the suggestion that these populations represent reproductively isolated cryptic species. (Abstract ID 10861)

PREDICTING THE IMPACTS OF CHANGING ENVIRONMENTAL CONDITIONS ON LOWER TROPHIC LEVEL ECOSYSTEM DYNAMICS IN THE BERING SEA

Despite frequently being ice covered until March the continental shelf of the eastern Bering Sea is one of the world’s most productive marine ecosystems, with its fisheries representing half of the marine harvest in United States waters. Large changes in lower trophic level ecosystem dynamics have been observed on inter-annual and inter-decadal time scales, although the mechanisms giving rise to these changes are not well understood. We present a lower trophic level ecosystem model for the Bering Sea that has been developed to explore relationship between climate, ocean conditions, productivity and flow of energy through the food web. The core of the ecosystem model is a Nutrient-Phytoplankton-Zooplankton model which has been coupled to an ice-biology module and to a benthic sub-model. This modeling effort is a major advancement in our understanding of the Bering Sea’s role in the global carbon cycle and thus its capacity for regulating climate feedbacks. Model predictions of the influence of future climate change on the ecosystem of the Bering Sea will be discussed and model predictions of the influence of changing environmental conditions on lower trophic level ecosystem dynamics in the Bering Sea presented. ENHANCEMENT OF REVERSE ESTUARINE CIRCULATION EVENTS AND COASTAL CONNECTIVITY DUE TO PLUME INTRUSIONS FROM AN ALONGSHORE ESTUARY

Connectivity between the coastal ocean and estuaries as well as between adjacent estuaries along a coastline can impact both the physics as well as the biology of these systems. Realistic hindcast ROMS simulations of the Pacific Northwest including the Salish Sea and Columbia River estuaries and the coastal ocean off Washington and Oregon show these connections. The Columbia River plume downwelling favorable winds can intrude into the Salish Sea via the Strait of Juan de Fuca. These frequent events reverse estuarine circulation in the Strait and create an important transport pathway between the nearshore coastal ocean and the Salish Sea. While observations of these interactions have been made previously, particle tracking, model dye releases, numerical experiments, and a detailed examination of the total exchange flow allow us to quantify the extent of the interaction between these two estuaries. In particular we find that wind alone can create these reversals, however the presence of the Columbia River plume strengthens the reverse estuarine circulation allowing for enhanced connectivity between the nearshore coastal ocean, the Columbia River and the Salish Sea. BIOPHYSICAL RESPONSE TO ENSO DIVERSITY IN THE EASTERN TROPICAL PACIFIC OCEAN

ENSO significantly influences atmospheric and ocean circulations in the Pacific sector, which it turn affect biological production and ecosystem characteristics. Much of our existing knowledge about the relationship between ENSO and biology is with respect to the classic El Niño, which has maximum warming in the eastern equatorial Pacific (EP). However, since the 1990s, there have been frequent occurrences of a new type of El Niño that has maximum warming in the equatorial central Pacific (CP). The impact of the latter on biology is not well understood. Biophysical responses in the eastern tropical Pacific to the 1997-98 and 2009-10 El Niño (i.e., the strongest EP- and CP-El Niño event in the last three decades, respectively) are analyed using satellite observations and reanalysis products. Significant differences in chlorophyll-a concentration are found between the two events associated with different patterns of anomalies for the physical variables. An adjoint tracer analysis is used to examine the difference in the origin and pathway of water masses in the upper eastern tropical Pacific that control the difference in nutrient supply and thus chlorophyll-a concentration. OXYGEN TRENDS IN THE GLOBAL OCEAN

Global ocean models predict that, for realistic CO2 emission scenarios, the oceanic oxygen inventory should decrease about 3 times faster than what we would expect solely from the decreased oxygen solubility of warmer temperature. In addition, the need to produce ever greater quantities of food for a growing world population has driven to the widespread use of fertilizers in agriculture. This caused increased nutrient fluxes to the coastal ocean, where ensuing increases in primary productivity and in the vertical flux of organic matter are presumably the primary cause of decreasing oxygen near the bottom in several coastal settings. Yet it is often difficult to detect significant oxygen trends in the global ocean due to the lack of historical oxygen data and shortness of time series. Using a global ocean database, calculations reveal that median oxygen decline rates are more severe in a 30 km band near the coast than in the open ocean (>100 km from the coast). Percentages of oxygen time series with negative oxygen trends are also greater in the coastal ocean than in the open ocean. (Abstract ID 10869)

DYNAMIC CO2 ERRORS AS ESTIMATED FROM SHIP-BASED CTD CASTS, AND SOME MODELING

Near slack tide in the Saguennay fjord, three CTD casts with two optode 3830 sensors and one SBE43 sensor were performed at vertical descent and ascent speeds of 0.14, 0.30 and 1.0 m s-1 respectively. Winkler titrations were performed at ten depths immediately before and after this set of CTD casts. The difference in oxygen measurements between upcasts and downcasts was...
BIDIRECTIONAL REFLECTANCE DISTRIBUTION CORRECTION OF ABOVE-WATER AND SATELLITE WATER-LEAVING RADIANCE IN COASTAL WATERS

Water-leaving radiances, retrieved from in situ or satellite measurements, need to be corrected for the bidirectional properties of the measured light in order to make them comparable with each other. The current satellite operational algorithm for this correction is optimized for typical oceanic waters. In order to analyze the bidirectional reflectance distribution function (BRDF) of case 2 waters a dataset of typical remote sensing reflectances was generated through radiative transfer simulations for a range of viewing geometries. A case 2 water focused remote sensing reflectance model is proposed based on this dataset to correct above-water and satellite water-leaving radiance data for bidirectional effects. The proposed model is first validated with a year-long time series of in situ above-water measurements acquired by colocated multi- and hyperspectral radiometers with different viewing geometries installed at the Long Island Sound Coastal Observatory (LISCO) and then on MODIS data for the LISCO site. Following successful validation original dataset simulated for moderate case 2 waters a dataset of typical remote sensing reflectances was generated through radiative transfer simulations for a range of viewing geometries. A case 2 water focused remote sensing reflectance model is proposed based on this dataset to correct above-water and satellite water-leaving radiance data for bidirectional effects. The proposed model is first validated with a year-long time series of in situ above-water measurements acquired by colocated multi- and hyperspectral radiometers with different viewing geometries installed at the Long IslandSound Coastal Observatory (LISCO) and then on MODIS data for the LISCO site. Following successful validation original dataset simulated for moderate case 2 waters is expanded for a broader range of open ocean and coastal water parameters. (Abstract ID 10343)

NITROGEN ISOTOPES IN THE ORGANIC MATRIX OF BIVALVE SHELLS: A RECORDER OF ANTHROPOGENIC NITROGEN POLLUTION.

Stable nitrogen isotopes (δ15N) in organic tissues have been extensively used to detect anthropogenic nitrogen inputs into aquatic systems, as waste-water is typically enriched in 15N. However, it has been difficult to extend records of anthropogenic nitrogen input back through time. δ15N signatures in the organic matrix of bivalve shells offer the potential to extend such records to the past using museum collections or fossil specimens. Mytilus edulis shells from the highly polluted Scheldt estuary in the Netherlands were more enriched in 15N (δ15N = +13.3±0.5‰ n= 17) compared with Chlamys uniserialis shells from the less impacted Ouargueli River in the Central African Republic (4.4±0.5‰ n= 3). Pecten maximus shells from the French coast ranged from +8.3±0.6‰ in the Bay of Brest to +3.1±1.2% at 200m depth. Average δ15N shell and tissue 15N values were highly correlated along this depth gradient (shell=0.82*tissue+1.46, R2=0.94, n=4). These preliminary data suggest that the organic matrix of bivalve shells record environmental 15N values from rivers to estuaries to the ocean and can record anthropogenic nitrogen pollution across a large ecological gradient. OCEAN SURFACE SALINITY TEXTURE WITHIN THE SUBTROPICAL REGIME

The climatic view of the ocean surface salinity (OSS) constructed from over 50 years of ship-based observations depicts a smooth field of salty water delineating the subtropical regime. In contrast, model output; satellite derived sea surface height and ocean surface temperature; ship-based underway measurements of SST, OSS and hull mounted Acoustical Doppler Current Profiler, reveal an abundance of mesoscale and sub-mesoscale structures. The meltane of ~100 km diameter eddies of salty and fresher components, along with larger scale circulation and Ekman convection, are fundamental in compensating the regional net evaporation. The OSS in situ data are limited in spatial and temporal coverage. Aquarius now provides data that reveal the source and evolution of the mesoscale OSS features, allowing improved understanding of their role in balancing the subtropical hydrological cycle. THE IMPORTANCE OF NONLINEAR POPULATION DYNAMICS TO EARLY LIFE HISTORY STAGES OF MARINE FISHES

Long-term scientific surveys of the fish communities in the California Current System and the Northeast U.S. Continental Shelf System reveal striking differences between the dynamics underlying larval, recruitment, and adult life history stages. We use time series forecasting models to explore the temporal dynamics of over 100 fish stocks on Georges Bank and in the Southern California Bight. We demonstrate that, for larval fishes, exploited species are...

SMALL-SCALE HYDRODYNAMICS IN TIDAL RIVER JUNCTIONS IN THE SACRAMENTO-SAN JOAQUIN RIVER DELTA

In branching channel networks, such as might be found in estuaries, channel junction flow dynamics may dominate large-scale dispersion. We focus on the Sacramento-San Joaquin River Delta, the complex of tidal channels upstream of San Francisco Bay, analyzing the structure and variability of several junction flow features. Observations made in August 2011 at three junctions display complex small-scale hydrodynamics. A boat mounted Acoustic Doppler Current Profile transacted along the perimeter of each junction for seven to eight hours. With the acquired water column velocity and local temperature data, we examine time variability of small-scale flow features at tidal river junctions. Also, nine Android phone drifters were released throughout one day to survey how tidal river junctions may affect near-field dispersion. Inner junction dynamics seem highly variable over a few hours with the formation and decay of bores and separation, recirculation, and subduction zones. Although small relative to the total distance traversed by the drifters, these flow features may significantly impact drifter trajectories and large-scale dispersion. Small-scale junction flow features appear to be linked mostly to plan-form geometry and depth variations. (Abstract ID 12139)

IN SITU ELECTROCHEMISTRY IN EXTREME ENVIRONMENTS: FROM SEAFLOOR HYDROTHERMAL VENTS TO THE DEEP SUBSURFACE BIOSPHERE

Numerous recent advances in ocean science research have been enabled by the development of technological engineering capabilities coupled to the adaptation of cutting edge sensor methodology. Electrochemical methods have often been used to study environmental processes, and in recent years there have been significant advances allowing for real time geochemical measurements with high temporal and/or spatial resolution. One such powerful technique is that of in situ voltammetry, where current is measured while scanning an entire voltage range of the solid-state mercury/gold electrode, allowing the simultaneous measurement of more than one species at a given time. Voltammetry is particularly useful for addressing questions of reductive species distribution and transformation rates at seafloor hydrothermal systems, however significant engineering and methodological challenges exist. Presented here are recent results and lessons learned from a series of deployments of a multi-parameter in situ electrochemical analyzer on DSV Jason-II and DSV Alvin at active vent sites on Loihi Seamount, Hawaii, and CORK Subseafloor Observatories located atIODP boreholes on the Juan de Fuca Ridge Flanks. THREE YEAR TIME-SERIES OF CARBONATE CHEMISTRY DYNAMICS AND BIOGEOCHEMICAL PROCESSES WITHIN A TROPICAL ATLANTIC CORAL REEF ENVIRONMENT

A three-year time-series of autonomous observations of air-sea pCO2 temperature, salinity and oxygen have been acquired within the La Parguera Marine Reserve, Puerto Rico at the Atlantic Ocean Acidification Test-bed. These observations, obtained using a MAPCO2 system, are coupled with autonomous meteorological (wind, rain), and light (PAR) measurements acquired at the near-by ICON/CREWS station. Together with weekly discrete carbonate chemistry sampling, we apply this time-series to explore the temporal dynamics and primary controls on carbonate system within a shallow water Atlantic tropical reef environment and consider how such dynamics might change as a consequence of continued ocean acidification. IN THE UNDERGRADUATE CLASSROOM

New participatory courses in Marine Sciences are now a central component of the Rutgers undergraduate Marine Science curriculum. The courses use new datasets enabled by ocean observations, in particular, the interactive exploratory capabilities of underwater gliders. The overall program is designed to increase repeated contact with students similar to the graduate experience. The main sequence is a 1.5 credit research course with changing topics that can be taken multiple times throughout the undergraduate career. Three levels of participation have been documented, starting with a "watch-one" phase, where students are learning to be part of a research team, a "do-one" phase, where students are active researchers, and a "teach-one" phase, where senior-level students act as mentors to the younger students. Initial feeder courses are used to involve students as early as their freshman year, with topics ranging from introductory overviews to initial skills building courses for research. A capstone course is Communicating Ocean Science, where students learn and have participatory experience in communication to informal audiences. Results include a 10-fold increase in undergraduate participation in the research lab. (Abstract ID 12386)

IMPACT OF OCEAN OBSERVATIONS ON HURRICANE IRENE INTENSITY FORECASTS

Hurricane Irene followed a track that curved northward over the Bahamas and ran directly over the U.S. east coast from Cape Hatteras to New England, causing severe storm surges and intense inland flooding. While the ensemble of atmospheric forecast models accurately forecast the track, intensity was consistently over predicted. IOOS data are used to better understand the intensity forecast. The highly stratified Mid Atlantic waters were monitored with a pair of gliders during the hurricane, documenting the rapid cooling and mixing of the warm surface layer with the cold pool, resulting a deeper thermocline and cooler surface waters. Satellite imagery revealed the greatest cooling at midshelf, where the availability of cold pool water is greatest. Atmospheric hindcasts of Hurricane Irene using the observed variation in sea surface temperature reduce the intensity of the storm, in some cases by 15 knots, bringing the hindcasts in line with buoys observations. Beyond the initial wind forcing, HF Radar surface current and drifter observations indicate the inertial tail of the storm lasted for several days, and was most intense over the mid shelf region. The overall program is designed to increase repeated contact with students similar to the graduate experience. The main sequence is a 1.5 credit research course with changing topics that can be taken multiple times throughout the undergraduate career. Three levels of participation have been documented, starting with a "watch-one" phase, where students are learning to be part of a research team, a "do-one" phase, where students are active researchers, and a "teach-one" phase, where senior-level students act as mentors to the younger students. Initial feeder courses are used to involve students as early as their freshman year, with topics ranging from introductory overviews to initial skills building courses for research. A capstone course is Communicating Ocean Science, where students learn and have participatory experience in communication to informal audiences. Results include a 10-fold increase in undergraduate participation in the research lab. (Abstract ID 12386)
Increased freshwater input into the Nordic Seas could ultimately lead to changes in the Atlantic Meridional Overturning Circulation. Freshwater anomalies in the Nordic Seas are often more strongly influenced as connected to the inflow from the Arctic, which is modulated by anomalous Arctic-river runoff as well as by net melting of Arctic sea ice and Greenland ice cover, and hence strongly influenced by global warming. We investigate Nordic Seas’ freshwater anomalies in a hydrographic dataset collected within the NISE project and show that those anomalies are mainly located in the Norwegian Sea. This location suggests a connection with the Arctic rather than the Arctic inflow. The routing of freshwater deduced from the observations is compared with that of a multi-century Bergen Climate Model simulation. Here, preliminary results show that the Arctic inflow dominates the Nordic Seas’ freshwater budget. The implications for the role of Arctic vs. Atlantic inflow on Nordic Seas freshwater anomalies both in predictions and future climate change are discussed. (Abstract ID 10952)

EFFECTS OF NUTRIENTS FORMS, RATIOS AND STOICHIOMETRY ON PELAGIC AND BENTHIC PROCRoccus spp.

The genus Procroccus includes six planktonic species that form high-biomass blooms, and at least nine predominantly benthic toxogenic species. Four of the planktonic, including P. minimum, the only plankton reported to be toxogenic, are among the most commonly recognized harmful algae that are increasing in frequency, duration, and magnitude globally. Growth studies suggest a species group that generally grows maximally at inorganic nutrient N:P ratios just below Redfield proportions. However, field studies indicate that planktonic Procroccus species bloom when nutrients are at high N:P ratios relative to Redfield proportions. In the benthic species P. lima complex, toxin production has been shown to be inversely related to nutrient limitation, increasing when nutrient ratios are above Redfield proportions. Mixotrophy and allelopathy can play an important role in the interactions among planktonic Procroccus species, diatoms and other dinoflagellates, but little information is available for benthic taxa. Given the projection for increasing land-based nutrient export to continue, it is expected that there will be further expansion of planktonic harmful Procroccus spp, and globally more intensive or more toxic benthic occurrences in the future. REEF BUILDING CORALS RELY ON SYMBIOTs FOR ENERGY AND NUTRIENTS OVER A LARGE DEPTH RANGE

Corals living in shallow waters typically acquire their nutrients and energy from their photosynthetic symbiotic zooxanthellae, whereas deeper corals may rely to a lesser extent on photosynthetic derived materials due to lower light levels. Whether these deeper corals feed to a greater extent is hotly debated within the community. We separately measured the stable carbon and nitrogen isotope signatures of the coral host and symbiotic zooxanthellae of three species of reef building corals (Porites astreoides, Montastraea cavernosa, and Montastraea faveolata) along a depth gradient (3–40 m) of the Florida Reef Tract. The δ13C and δ15N values of the zooxanthellae and host tissue of all three species became progressively more depleted in 13C and 15N with depth. The lower δ15N values at depth suggest that feeding is actually less important at depth. Further, we found a strong correlation between the δ13C values of the host and their zooxanthellae at all depths, suggesting that even as photosynthetic rates decrease with depth, hosts continue to acquire most of their carbon from their symbionts and do not rely to any greater extent on feeding heterotrophically. (Abstract ID 10436)

ASSESSING THE IMPACT OF OCEAN ACIDIFICATION ON MARINE PLANKTONIC CALCIFICATION USING SATELLITE ANALYSIS AND EARTH SYSTEM MODELING

Marine planktonic calcifiers such as coccolithophores, foraminifera, and pteropods play a fundamental role in the ocean carbon system, a role that may be modified substantially by rising atmospheric CO2, and climate change. We will present results from the initial phase of this study to better constrain the magnitude of ocean acidification and climate change impacts on marine inorganic carbon dynamics. In particular we will present improvements to our primary numerical tool, the new Community Earth System Model, version 1 (CESM v1), a variant of the widely used Community Climate System Model (CCSM) that includes fully interactive marine ecosystem and global carbon modules. Comparisons will be made to the earlier version (CCSM v3.0) coccolithophore fields as well as to historical satellite remote sensing (SeaWIFS, MODIS). Characterization of the biogeographic niche for marine calcifiers; i.e., the temperature, circulation and seawater chemistry `phase-space` for calcifiers will be shown. (Abstract ID 9542)

BOTTOM-UP EFFECTS ON INTERANNUAL VARIABILITY

Differences in surface area-to-volume ratio as a function of phytoplankton size are often reflected as different half-saturation constants for nutrient uptake. We consider the impacts of this difference for the interannual variability of different size classes of phytoplankton. We compare two models with allometric grazing of different size classes. In one model (described in Galbraith et al., Biogeosciences 2010) the growth rates of large and small plankton are set equal to each other. In the other different nutrient limitation is allowed. We examine the impacts of the differing formulations on interannual variability, showing that the bottom-up effects enhance interannual variability in large plankton during the spring, but suppress it during the fall. We examine the reasons for this difference, paying particular attention to the difference in the light-driven spring bloom versus the nutrient-driven fall bloom. (Abstract ID 11280)

DEFINING THE NICHE OF HARMFUL ALGAE VIA ECOGENOMICS AND TRANSCRIPTOMICS

Despite considerable efforts, a comprehensive understanding of the factors that promote these harmful algal blooms has been lacking because the biochemical pathways that allow their dominance relative to other phytoplankton within specific environments have not been identified. We sequenced the first HAB genome (A. apophagophernes) and compared its gene complement to those of six competing phytoplankton species identified via metaproteomics. Using an ecogenomic approach, we specifically focused on the genes that may facilitate dominance within the environmental conditions present during blooms (high levels of organic matter, metals, and turbidity). A. apophagophernes possesses a larger genome (56 mbp) and more genes involved in light harvesting, organic carbon and nitrogen utilization, and encoding siderophore- and metal-requiring enzymes than competing phytoplankton. Collectively, these findings suggest that anthropogenic activities resulting in elevated levels of turbidity, organic matter, and metals have opened a niche within coastal ecosystems that ideally suits the unique genetic capacity of A. apophagophernes and thus has facilitated the proliferation of this and potentially other HABs. Testing of this hypothesis via transcriptomics will also be discussed. (Abstract ID 11690)

A NEW TYPE OF WAVE MOTION IN INHOMOGENEOUS, COMPRESSIBLE FLUIDS IN A GRAVITY FIELD

We consider a particular class of wave motions in fluids, in which pressure remains constant in each moving fluid parcel. An exact, analytic solution of linearized hydrodynamics equations obtained is described that describes the wave motion in inhomogeneous, compressible, rotating fluids with piece-wise continuous parameters in a uniform gravity field. The solution is valid under surprisingly general assumptions about the environment and reduces to some classical wave types in appropriate limiting cases. Free waves in bounded and unbounded domains as well as excitation of wave fields by a point source are considered. Edge waves propagating along vertical and inclined rigid boundaries are found in rotating and non-rotating fluids. Allowance for three-dimensional variation of the sound speed and for arbitrary density stratification, including density discontinuities, makes the exact solution an attractive model of acoustic-gravity waves in a coupled ocean-atmosphere system. The new wave type complements classical exact solutions known as the Rossby, Lamb, Kelvin, and Poincare waves, which provide much of the conceptual foundation of modern geophysical fluid dynamics. LINKING PHYTOPLANKTON BIODIVERSITY AND PRODUCTIVITY IN AN ECOSYSTEM MODEL OF THE CALIFORNIA CURRENT SYSTEM
A self-emergent ecosystem model that strives to represent phytoplankton diversity of the California Coastal System (CCS) is utilized in order to resolve the relationship between primary productivity and species richness. In a numerical experiment, biomass and rates of productivity were calculated for a series of model runs that included monoucultures or polycultures of individuals drawn from the top 10 phytoplankton that emerged from a complete model run (n=78 phytoplankton). More than one phytoplankton type was necessary to maximize modeled resource use and productivity, as evidenced by over yielding in the polyculture. As a result, we identify a minimum of four phytoplankton types necessary to adequately capture modeled primary productivity in the CCS, and discuss the ecological mechanisms (e.g., complementarity, facilitation, selection) that structure the modeled phytoplankton community. A SHIP-BASED INSTRUMENT FOR THE DISCRIMINATION OF PHYTOPLANKTON TAXA USING SPECTRAL FLUORESCENCE SIGNATURES AND IMAGING MULTIVARIATE OPTICAL COMPUTING (IMOC)

Research continues on the development of an instrument for the in situ discrimination of phytoplankton size and community composition that is simple, relatively inexpensive, and has a low power requirement. A ship-based version has been constructed and tested in the field at Martha’s Vineyard Coastal Observatory (MVCO). The key components of the instrument are interference filters (called multivariate optical elements; MVEs) that are based on the principle of spectral fluorescence combined with multivariate optical computing for pattern recognition. These have been designed, constructed, and used to classify Synechococcus spp. (a PE-containing cyanobacterium), Thalassiosira pseudonana and T. weissflogii (diatoms), Emiliana huxleyi (a coccolithophore), and a Tripedella genotype. Data collected at MVCO are consistent with those from the Imaging FlowCytob and with respect to cell concentrations and approximate cell sizes. Work continues on background and flat-field corrections to improve our detection of the smallest cells (e.g., Synechococcus). (Abstract ID 11881)

INCREASED ABUNDANCE AND ECOLOGICAL IMPLICATIONS OF PLASTIC MICRODEBRIS IN THE NORTH PACIFIC SUBTROPICAL GYRE

Reports of plastic debris in the North Pacific Subtropical Gyre (NPSG), particularly microdebris less than 5 mm in diameter, have been cause for significant public concern. However, the distribution, abundance, and ecological effects of pelagic plastic debris remain largely unknown. We compared neat samples from 1972-3 to those collected in 2009-2010. The median concentration of neutrionic plastic microdebris increased from 0.001 particles m^{-2} in 1972-3 to 0.310 particles m^{-2} in 2009-2010. Microdebris particles were inhabited by a subset of the North Pacific Subtropical rafting community, and associated with increased abundance of the pelagic insect Halobates sericeus. In a series of 24-hour incubation experiments, neutrionic zooplankton ingested polyethylene spheres 25-35 μm in diameter. These results are a first step to understanding the ecological implications of microdebris in the NPSG. (Abstract ID 10407)

LIMITS TO DISPERAL FOR MARINE PLANKTON

Distributional range shifts are one of the primary biological responses to climate change expected and observed among marine plankton species. However, plankton must have sufficiently high dispersal potential to be able to track spatial changes in their ocean habitat. Here we examine the genetic-geographic structure of a cosmopolitan planktonic copepod, Haloptilus longicornis, across a basin-scale longitudinal transect in the Atlantic Ocean (48° N – 44° S), in order to evaluate the dispersal capacity of this species across a number of environmental gradients. We find that although the species is present throughout subtropical and tropical waters in the Atlantic, a region of low abundance in equatorial latitudes corresponds to a population genetic break in this species (Fst = 0.17, P < 0.005). Our results imply limited dispersal across the tropics, and the genetically intermediate population in this region must contribute few migrants to populations in the northern and southern subtropical gyres. We conclude with the suggestion that regions of sub.visual, in which the species consistently occurs in lower abundance, may serve as important dispersal barriers for holoplankton species. TRANSITION IN THE GLOBAL GEOMETRY OF ARCTIC MELT PONDS

During the Arctic melt season, the surface of the ice cover undergoes a remarkable transformation from vast expanses of snow covered ice to complex mosaics of ice and melt ponds. Sea ice albedo, a key parameter in climate and ecosystem modeling, is determined by these configurations. We have found that melt pond evolution exhibits a critical transition from simple Euclidean shapes to self-similar regions with boundaries similar to space filling curves of fractal dimension 2. The critical length scale in terms of area is around a hundred square meters. Our findings demonstrate that there are universal features of Arctic melt pond evolution which are similar to phase transitions in statistical physics, and provide a novel path to simplify the treatment of melting sea ice in climate models. SHRINKING SNOW CAPS AND RISING TIDES - RESPONSE OF THE ARABIAN SEA ECOSYSTEM TO CLIMATE CHANGE

Over the past 10 years the Arabian Sea ecosystem has witnessed rapid changes linked to the warming trend over Eurasia. Since 1998, the warming trend has led to intensification of wind-driven upwelling along the coasts of Somalia, Oman and Yemen and record increases in...
phytoplankton blooms over the entire western Arabian Sea. The impacts of the warming trend have not been limited to the southwest monsoon. Since 1998, winter convective mixing during the northeast monsoon (NEM) has been weakening, but despite this trend, Chl concentrations in the Arabian Sea have been on the rise due to unprecedented blooms of the green heterotrophic dinoflagellate Noctiluca scintillans. Thick blooms of Noctiluca have become a regular feature of the Arabian Sea during the NEM, replacing diatoms as the dominant winter-bloom forming phytoplankton. Here we present eco-physiological data from several cruises to the Arabian Sea which suggests that the appearance of this organism may be tied to the shoaling of oxygen deficient waters in the northern Arabian Sea. The implications of this organism for food chain are also discussed. (Abstract ID 9924)

TIDAL WAVE REFLECTANCE AND NON-LINEAR TRANSFER IN THE ELKHORN SLOUGH, CA

Elkhorn Sough is a shallow, tidally-forced estuary directly connected to Monterey Bay. The short slough length and significant tidal storage due to flats and marshes create an ebb-dominated slough. Analysis of 10 days of co-located velocity and pressure observations measured in the Elkhorn Sough, CA, in 2009 revealed a 20% energy loss between the incoming and outgoing tidal wave. It was found that, energy from primary tidal constituents was transferred to higher harmonics making the outgoing wave different from the incoming wave. Owing to a lack of statistical confidence for the 10-day data set, four longitudinally placed co-located velocity and pressure sensors throughout the slough for 60 days in September to October of 2011. The new time series are separated into incoming and outgoing tidal waves by using the cross-spectral analysis of co-located pressure and velocity data. Tidal wave reflectance, as a function of frequency for the tidal constituents and corresponding overtides, dissipation rates between each station, and non-linear transfers using a bi-spectral analysis will be presented. (Abstract ID 9758)

WIND INDUCED CHANGES ON THE AGULHAS SYSTEM

The connection between Indian Ocean and South Atlantic at the Agulhas retroflection area is limited to the south by the Subtropical Front, and is largely controlled by the location of the zero wind stress curl. Since the late 1960s, the circumpolar westerlies have been showing a poleward shift in response to the positive trend of the southern annular mode (SAM). To access the impact of these changes of the atmospheric forcing on the Agulhas region, an implementation of the HFCOM, forced with monthly means of NCEP/Reanalysis since 1948 was run. The results show a positive trend in sea surface height, salinity and temperature from 1970 to 2010. The model results also show a poleward shift of the Subtropical Front. The positive trend of these fields in the Agulhas System region and the displacement of the Subtropical Front follow the positive trend of the SAM index, with higher values during austral summer months. These changes reflect a southward drift of the wind forced ocean gyres, and a widening of the connection between the two basins. (Abstract ID 10608)

OBSERVATIONS OF CIRCULATION AND WATER MASS TRANSFORMATION IN THE EASTERN CHUKCHI SEA

Pacific water enters the Chukchi Sea through Bering Strait and progresses northward, impacting aspects of the western Arctic Ocean including ice-melt and ventilation of the upper halocline. In summertime the Alaska Coastal Current (ACC) is the major conduit for warm and fresh Pacific Water. However, to date there have been limited direct observations of the current. Here we use hydrographic and velocity data from multiple summertime surveys to investigate the circulation and intra-seasonal variability of water masses in the Chukchi Sea, with emphasis on the ACC. Contrary to earlier thinking, we demonstrate that the ACC is at times weakly baroclinic, highly variable along the shelf, and can transport multiple water masses that can be objectively defined based on their physical properties. We argue that, in early summer, mixing between surface ACC water penetrating the Chukchi Sea and winter water already on the shelf leads to the formation of a new water mass. This Chukchi Summer Water has the correct density to ventilate the upper halocline, potentially weakening its ability to insulate the deeper warm Arctic water. (Abstract ID 10755)

PHOTOSYNTHESIS-IRRADIANCE RELATIONSHIPS IN SEAWATER OF THE EAST CHINA SEA IN THE CONTRAST SEASON (WINTER AND SUMMER)

Photosynthesis-irradiance relationship (P-E curve) of marine phytoplankton is the key factors for the estimation water column primary production based on satellite ocean color information. P-E curve can be described by an equation with two parameters, the maximum rate of photosynthesis (Pm) and the initial slope (α). On board incubation of P-E curves were carried out from January and July cruises of 2008 in the East China Sea. The January and July cruises were designated to represent the winter and summer conditions, respectively. In winter, only little variation of (Pm,α) were found due to the well-mixed conditions in the euphotic layer. In summer, very high variation of (Pm,α) were found due to the strong stratified conditions in the euphotic layer. The shelf-averaged values of (Pm,α) in the shallow mixed layer were in general higher than the values below the mixed layer. The shelf-averaged values of water column primary production calculated based on the photosynthesis-irradiance relationships were 186±117 and 775±677 mgC·m⁻²·d⁻¹ in winter and summer, respectively. The results further demonstrated the overestimation of standard products of satellite-based primary production. In addition, the spatial distribution of measured primary production was counter to the satellite-based primary production in winter. (Abstract ID 9697)

NUMERICAL INVESTIGATION OF COASTAL CIRCULATION DYNAMICS NEAR CAPE HATTERAS, NORTH CAROLINA

Coastal circulation near Cape Hatteras (CH), North Carolina is highly complex due to the convergence of the shelf currents, presence of several ocean fronts and influence of the Gulf Stream. While the interaction of shelf flows with the Gulf Stream is of tremendous importance as it often results in significant export of coastal water to the deep ocean, the dynamics of this interaction are not well understood. In this study, we used a nested regional ocean model to hindcast circulation states in summer (August, 2004) and winter (January 2005) periods, when extensive coastal sea level, in situ temperature, salinity and velocity observations are available. Model-data comparisons show major features in the observations are reasonably well simulated, allowing us to perform detailed analyses on along- and cross-shelf transport, momentum and kinetic energy balances to further quantify complex circulation variability and shelf water entrainment processes near CH during these two periods. In this presentation, we will describe our model setup and model skill assessments, and discuss major findings derived from these model diagnoses. (Abstract ID 11637)

DELIVERY AND ACCUMULATION OF PARTICULATE ORGANIC MATTER ALONG THE WEST COAST OF NORTH AMERICA: THE IMPORTANCE OF SMALL MOUNTAINOUS RIVERS

We investigate the concentration and biogeochemical composition of particulate organic matter (POM) in the suspended load of three small mountainous rivers from the west coast of the United States (Umpqua, Eel and Salinas) and in surface sediments from their associated depositional rivers located adjacent to the shelf. Samples collected at different fluvial discharges, including several flood events, and at different locations and water depths along the shelf were analyzed for a variety of parameters to evaluate POM provenance and composition. Measurements include carbon and nitrogen contents, stable carbon and nitrogen isotopic compositions, radiocarbon compositions and yields of organic compounds derived from
distinct biologic (e.g., biomarkers such as lignin phenols, cutin acids, amino acid products) and combustion (e.g., pyromarkers such as polycarboxylated benzenes) sources. These data are used to compare and contrast the source, age, and biochemical make-up of POM transported and deposited by each river system. Because the river systems have distinct hydrodynamic, geomorphology, hydrology and land use patterns, and their associated shelves display significant contrasts in oceanographic characteristics such as wave energy, currents, productivity and bathymetry; we use the observed trends to gain insights on the factors that control the delivery, transformation and fate of organic matter across this continental margin. CARBON DIOXIDE FLUXES IN THE EASTERN NORTH ATLANTIC DURING SUMMER AND AUTUMN: A COMPARISON BETWEEN 2006 AND 2011

In the framework of the CARBOCHANGE Project, the variability of fugacity of CO₂ in the Eastern North Atlantic region is being studied using a voluntary observing ship. The QUIMA

CONTROL PROCEDURE TO ESTIMATE ERROR COVARAINCES

The error variance of an analysis is an important piece of information that is often required by users. However, accurate calculation of this usually relies on good knowledge of the error covariances of the background field and observations that were combined to make the analysis. These may not be available for all locations. We outline an approach to obtaining analysis uncertainty that does not depend on knowledge of these error covariances. The approach uses a special analysis that indicates the influence of observations at each analysis grid point. This is then converted to analysis error variance using coefficients that are estimated from the data that formed the analyses. The approach is demonstrated for the objective analyses of the EN3 dataset. These are monthly estimates of the temperature and salinity of the ocean running from 1950 to present. However, the method would be applicable to other variables and other spatial and temporal scales. It is also shown that the approach has the benefit of highlighting areas where there may be problems in the analyses. (Abstract ID 9686)

IMPACTS OF TEMPORAL CO₂ AND CLIMATE TRENDS ON THE DETECTION OF OCEAN ANTHROPOGENIC CO₂ ACCUMULATION

While the oceanic CO₂ sink is estimated to be 25% of annual emissions, this is likely to decrease over the next 100 years as ocean temperatures increase and the ocean becomes saturated with CO₂. Currently oceanic anthropogenic carbon dioxide (AnthroCO₂) is approximated by linear relationships between dissolved inorganic carbon (DIC) and a suite of physical and biological ocean parameters. This technique depends on stable regression residuals through time. However, non-linear increases in DIC due to long-term trends in the physical and biological state of the ocean may result in an unstable relationship. In our study, the validity of these assumptions over the 21st century is tested using the Climate Community Systems Model, to simulate natural and anthropogenic DIC. Our results indicate that at sampling intervals of 3 decades this method should be used to predict AnthroCO₂ as errors will have reached ~20%. As we approach the 30th anniversary of WOCE occupations, it is imperative that we continue to pursue field measurements to detect changes in AnthroCO₂ in the ocean and that we continue at regular intervals of no less than 10 years if the error is to remain below 20% for many regions in the ocean, including the Southern Ocean, tropical Atlantic Ocean, tropical Pacific Ocean, and North Atlantic Ocean. SUBMESOSCALPE SPATIAL VARIABILITY OF OCEAN TURBULENCE

As a part of the June 2011 ONR Scalable Lateral Mixing and Coherent Turbulence (LatMix) experiment, a detailed characterization of the spatial structure (both vertical and horizontal) of velocity and temperature turbulence (microstructure) was obtained. The experiment took place in the Sargasso Sea, approximately 300 km SW of Cape Hatteras. The approach was to use the T(turbulent)- REMUS Autonomous Underwater Vehicle navigating in a box pattern around a drifting drogued Gateway communication buoy. The vehicle was employed in a yoyo mode spanning depths of 20 to 45 m using a 30o descent/ascent angle. This configuration allowed the AUV based measurements to be both along and across prescribed isopycnals and to be taken in an approximate Lagrangian coordinate system with respect to the mean flow at the center depth of the drogue. An intrusion of cold fresh water was observed on the sigma theta = -25.1 kg/m³ surface and tracked for 14 km. Sporadic regions of intense turbulence were found at the vertical edges of the intrusion suggesting a shear driven source of the turbulence. Turbulence patches within the cold plume were much less intense and less intense. A discussion of processes involved in both cross and along isopycnal mixing will be presented. (Abstract ID 9343)

EASY ELECTRONICS FOR TEACHING OCEAN SCIENCE

Modern ocean science depends heavily upon electronic devices, such as multibeam sonar, CTD instrumentation, remotely operated vehicles, and broadband satellite communications. While such sophisticated devices are often operated and maintained by skilled electronics technicians, it is useful for ocean scientists to have a working acquaintance with the basic principles and methods on which these devices are based, since such knowledge may suggest novel ways of approaching a wide variety of research problems. This presentation demonstrates a number of simple and relatively inexpensive devices that can be acquired by ocean scientists to complement existing undergraduate ocean science courses, as well as in student projects or actual fieldwork. STATE ESTIMATES AND FORECASTS IN THE GULF OF MEXICO

An adjoint method analysis has been developed for the Gulf of Mexico (GoM) and has been tested by forecasting Loop Current (LC) and eddy shedding. State estimation (also called four-dimensional variational (4D-VAR)) was used to match the model evolution to satellite-derived along-track sea surface height (SSH) anomalies and gridded sea surface temperature (SST) data by adjusting model temperature and salinity initial conditions, open boundary conditions, and surface forcing fields. The model fits observations during the assimilation period and forecasts ocean state using monthly climatological open boundary conditions and surface forcing. Forecasts provide a cross-validation test of the state estimate by comparing its evolution to independent observations. The model forecast was tested for several ring separation events, including Eddy Franklin (Eddy-F) in May 2010, during the Deepwater Horizon (DWH) oil spill in the GoM. The model skill has been assessed by computing model-observation root-mean-square (rms) differences during both the hindcast and forecast periods. The model forecast skill metrics generally outperform persistence, reference (unadjusted) model runs, and climatology during a LC ring-shedding event for a period of 1 – 2 months. MECHANISMS OF NON-PHOTOCHEMICAL QUENCHING OF FLUORESCENCE IN CYANOBACTERIA

Quantum yields of chlorophyll fluorescence recorded under ambient irradiance, including solar-induced fluorescence, are controlled by the process of non-photochemical quenching (NPQ), a photoprotective mechanism that dissipates excess absorbed energy as heat. All plants, eukaryotic algae, and many cyanobacteria evolved NPQ but the molecular mechanisms differ between taxa. The NPQ in cyanobacteria has only recently been discovered. Here we present a new model of NPQ in cyanobacteria and determine bio-optical, kinetic, and thermodynamic characteristics of this process. Our kinetic analysis revealed that NPQ is a multi-step process that includes both light and dark reactions. The NPQ is triggered by an orange carotenoid protein (OCP) that acts as a blue-green photoreceptor. Formation of the quenched state involves photoactivation of the OCP carotenoid, conformational change in the protein, and its attachment to phycochlorins. NPQ activates a pathway of thermal dissipation from allophycocyanin, thus reducing the flux of absorbed energy from phycochlorins to reaction centers. We compare the NPQ mechanisms in cyanobacteria with that in other phytoplankton taxa and discuss implications for interpretation of the irradiance-driven variability in fluorescence yields in the ocean. SEASONAL AND INTERANNUAL FLUCTUATIONS OF BOTTOM WATER EXPORT FROM THE WESTERN ROSS SEA

Long time series of ocean properties are increasingly important in assessing the ocean coupling and feedback to global climate change. The polar regions are particularly sensitive to climate change, including Southern Ocean deep ocean overturning. Export of AABW from the western Ross Sea was observed during the Cape Adare Long Term Mooring (CALM) program, February 2007 to January 2011. The CALM time series exhibits pronounced seasonal periodicity similar to that observed in Weddell Sea AABW export. The bottom maximum speeds and coldest temperature occur in March-April, suggesting austral summer/early fall export of shelf from the western Ross. Seasonally is also apparent in salinity, with the saltiest bottom water coinciding with the coldest bottom water. The warmest, freshest bottom water occurs in July-January, with a secondary cold period in October-November, which is not coupled to high salinity, suggesting an origin from the eastern Ross Sea lower salinity shelf water. Interannual decrease in bottom salinity is evident, reflecting a decadal decrease in regional shelf salinity and/or reduced contribution of western Ross Sea high salinity shelf water. SEISMIC IMAGING OF WATER MASS MIXING PROCESSES ASSOCIATED WITH THE SUBTROPICAL FRONT SOUTHEAST OF NEW ZEALAND

Water mixing processes across the Subtropical Front (STF) southeast of New Zealand’s South Island are poorly understood. However, such processes are readily apparent in this region due to observations of significant micro-nutrient transport (particularly iron) from subtropical to subantarctic water masses. Modern petroleum industry multi-channel seismic reflection data acquired near and across this front provide an opportunity to study such processes in two dimensions and at length scales of tens of metres. In particular, the structures of eddies that rotate off the front (locally manifested as the northeastward-travelling Southland Current) into subantarctic waters have been imaged on several seismic lines. A comparison has been made of two roughly coincident petroleum industry data sets collected across the front during the summers of 2005-2006 and 2007-2008. Distinctive eddy-shaped features have been imaged at a variety of sizes and with different amounts of internal reflectivity. The characteristics of the outer edges of these features provide some constraint on how the eddies interact with the surrounding water masses. (Abstract ID 10781)

SST-WIND COUPLED MODES IN THE BENGUELA CURRENT SYSTEM AT INTRASEASONAL TIME SCALES FROM SATELLITE OBSERVATIONS (2000-2008)

In this study a combination of reanalysis and satellite data is used to document the intraseasonal upwelling variability of the Benguela current system and its forcing mechanisms. A covariance analysis between winds (QuikSCAT) and SST (TMI) allows first documenting the spatial extent, seasonal modulation and intensity of the upwelling cells in two regions of peak variability of upwelling-favorable winds, namely the regions around Cape Frio (18°S) and Luderitz (27°S). The analysis reveals that dominant wind-SST covariability modes are associated with two distinct regimes: a high-frequency regime corresponding to the local atmospheric forcing of synoptic variability related to the extra-tropical storms activity and a low-frequency regime related to the propagation of equatorial Kelvin waves. The remote atmospheric and oceanic forcings are documented from the NCEP and SODA reanalyses. Results are discussed and compared to the characteristics of the intraseasonal upwelling variability in the Humboldt upwelling system (Peru/Chile region). (Abstract ID 11976)

HIGH-RESOLUTION PALEO-ENVIRONMENTAL CHANGES OBSERVED BY DETAILED XRF CORE SCANNING IN HOLOCENE (0-16 KA CAL. BP) SEDIMENTS FROM THE CENTRAL MEDITERRANEAN

The Mediterranean area is a sensitive recorder of climate change, as it is located on the boundary of the subtropical pressure fields and the mid latitude westerlies. This sensitivity makes it an ideal region for climate studies. Previous work in the Gulf of Taranto, (Central Mediterranean) has shown the prominent presence of millennial - decadal variability during the past 2000 years (e.g. Castagnoli, 1992). In this study, we present high resolution records of environmental change based on XRF core scan data and proxy data from a range of cores from the same region spanning different water depths and covering the last 16 kyr. We demonstrate significant changes in the hydrological cycle from glacial to interglacial times and on sub-millennial scale which are attributed to changes in river run-off as a result of changes in global atmospheric circulation patterns. ENSEMBLE APPROACH TO FORECAST SATELLITE BIO-OPTICAL PROPERTIES AND UNCERTAINTIES

We apply an ensemble approach to produce short-term (1-3 day) forecasts and associated confidence in the forecast. We developed ensembles for two types of models, hydrodynamic and/or initial field), the ensemble spread (variance) provides an indication of uncertainty, or community to propagate initialization, forcing, and algorithm error sources through the numerical models. Ensemble techniques have been used by the environmental modeling community to propagate initialization, forcing, and algorithm error sources through the simulation process. When each ensemble member uses a different realization (e.g., forcing and/or initial field), the ensemble spread (variance) provides an indication of uncertainty, or confidence in the forecast. We developed ensembles for two types of models, hydrodynamic only (no biology) and coupled bio-physical models, to assess the importance of including biogeochemical biology in the simulations (i.e., whether the particles can be treated as conservative tracers or whether inclusion of growth and grazing is required). We compare the forecast distributions to the corresponding satellite ocean color image products and calculate spread-skill statistics.
to assess the skill of the model forecasts, and how well the ensemble variance represents forecast uncertainty (whether the largest ensemble variances correspond to the largest forecast-observation mismatches). This methodology enables us to quantify errors and produce uncertainty maps for bio-optical forecasts. (Abstract ID 10272)
DO SOUTHERN OCEAN FRONTS FOLLOW MERIDIONAL SHIFTS IN THE SOUTHERN HEMISPHERE WESTERLY WINDS?

The detectability of Southern Ocean fronts and their response to climate change is analyzed in a 100 year CO2-induced climate change simulation using the high resolution coupled climate model HIRHAM.1. Fronts are identified as local maxima in the surface sea height and sea temperature (SST) gradient, and zonal transport. These methods agree well, except for regions near Antarctica where background SST gradients weaken and north of the Antarctic Circumpolar Current (ACC) where SST gradients can be density compensated by salinity gradients. As the climate warms, the maximum wind stress increases by a zonal average of 13 percent and shifts south by up to 10 degrees locally. The Subtropical Front shifts south accordingly, even over steep topographic ridges. However, no displacement of fronts in the ACC is found and the current contracts and weakens despite the increased wind stress. Front location and intensity appear strongly controlled by topography. While the position of ACC fronts remains fixed there are changes to the properties of water-masses between frontal zones. The implication for the detection of frontal shifts in paleo records is discussed. (Abstract ID 11279)

LAST DECADES SEA SURFACE TEMPERATURE CHANGES AND TRENDS IN SOUTHWESTERN OF SOUTH ATLANTIC OCEAN USING AVHRR SATELLITE DATA AND MODEL SIMULATION

The understanding of the South Atlantic Ocean has become very useful since its circulation compounds the upper path of Meridional overturning circulation, playing an important role on global climate system. Recent researches show that Southwestern South Atlantic is becoming warmer and saltier during past decades (Curry & Mauritzen, 2005; Sato & Polito, 2008). Using model simulation, this work investigated this warming and its influence on Southeast Brazilian Coast, specially on Brazil Current (BC) retroflexion, where it separates from the coast to flow eastward, compounding the lower boundary of South Atlantic Subtropical Gyre. The model used is HYCOM and reproduces South Atlantic Ocean conditions from 1960 to 2010, forced by NCEP Reanalysis. In this study we also compare sea surface temperature of satellite data (AVHRR Pathfinder v.5) with model results. At first, satellite data from 1980 to 2010 seem very similar to model results for the same period. Trends in latitude of the BC retroflexion are approximately 0.015° and 0.025° per year southwest, to model and satellite, respectively. With this result is possible to estimate that the South Atlantic Subtropical Gyre is transcribing its south limit, so do the influence of warm water transported by BC at upper levels. AN INNOVATIVE METHOD FOR THE DETERMINATION OF TRACE ZINC IN SEAWATER USING MICRO-SEQUENTIAL INJECTION AND A NOVEL FLUORESCENT PROBE

Flow Injection (FI) technology has been considerably improved over the last two decades notably with the development of miniaturized, single channel discontinuous flow systems. This presentation will describe the principles and attributes of micro-Sequential Injection lab-on-valve (µSI-LOV), the latest development in FI methodology, and its application to the determination of trace Zn in seawater samples. The technique exploits the selectivity and sensitivity of RuO2-Zn-3, a novel fluorescent probe that is used in a seawater matrix for the first time. The optimized reaction conditions and flow protocol yield a detection limit of 0.3nM Zn, high precision (RSD ≤ 2.5%) and a linear quantification range up to 40nM Zn. This is achieved without preconcentration using 50µL of indicator and 75µL of sample, an analytical cycle of 1min per sample and instrumentation that is simple, compact, fully automated and requires minimal maintenance. The applicability of µSI-LOV to open ocean determinations will be demonstrated using SAFE standards and open ocean Zn profiles collected in the Southern Ocean. The potential of µSI-LOV to shipboard and eventually in situ determinations of trace elements will also be discussed. (Abstract ID 10845)

DISTINCTION OF ATLANTIC VS. PACIFIC NITRATE IN THE BEAUFORT SEA FROM THE COUPLED N AND O ISOPTIE RATIOS OF NITRATE

We present the first measurements of the natural abundance nitrogen (N) and oxygen (O) isotope ratios of nitrate (15N/14N and 18O/16O) from water-column depth profiles collected along a transect in the Beaufort Sea, during the Canadian IYP-GEOTRACES cruise aboard the Admiration in August-September 2009. The data show a clear distinction of nitrate from Atlantic vs. Pacific provenance. Nitrate isotope ratios below the halocline are analogous to those measured by others in the North Atlantic. A substantial increase in nitrate 15N/14N is evident from the bottom of the halocline toward the surface, paralleled by a comparable decrease in nitrate 18O/16O at these depths. But the record of 15N/14N shows that the 15N-enriched nitrate observed in the upper open ocean is confirmed to nitrate exported to the Arctic at Bering Strait due to benthic denitrification on the Bering shelf; Evidenced of this is afforded by previous observations of progressive 15N-enrichment of fixed N on the eastern Bering shelf in association with the N deficit (Granger et al. JGR in press). The decrease in nitrate 18O/16O in the Beaufort halocline toward the surface indicates that nitrate is newly nitrified toward the surface, such that 100% at the nitrate at the concentration maximum was assimilated then remineralized directly in the Arctic. The nitrate isotope ratios thus provide a unique tracer of Pacific-derived N into the Arctic, and provide insight of N biogeochemical transformations that occurred on the Bering shelf and downstream in the Arctic. CHANGES IN TERRESTRIAL CDOM ABSORPTION SPECTRAL SLOPES WITH MIXING AND REMOVAL (HUDSON BAY, CANADA)

We examine the changes in absorption spectral slopes of colored dissolved organic matter (CDOM) using a data set of salinity, δ15N and δ18O and CDOM absorption in Hudson Bay (Canada). CDOM in Hudson Bay is controlled by terrestrial inputs, in contrast to adjacent Hudson Strait. By following the fraction of river water (determined with salinity and δ15N/δ16N) we track the changes in terrestrial CDOM optical properties with mixing and removal. CDOM absorption is removed to a significant degree likely due to photochemical oxidation, and indicates that terrestrial inputs of DOM are labile. There was no negligible indication of absorption removal during initial estuarine mixing. Of the many absorption spectral slope (S) parameters used as proxies for CDOM dynamics, the ones at shorter wavelengths proved the best indicators for absorption removal. Increase in absorption spectral slopes at 275 to 295 (S275-295) and 290 to 350 nm (S290-350) are strongly correlated with removal of CDOM absorption. (Abstract ID 9389)

COHERENT MEASUREMENTS OF OCEAN SURFACE WAVES AND WIND FOR HIGH WIND AND WAVE CONDITIONS.

Current wind-wave numerical models are largely based on a statistical description of the marine atmospheric boundary layer (MABL) and do not resolve the phase of the waves nor the modulation of the wind by the waves, but the next generation of LES models will provide wave-resolved dynamics, kinematics and the coherent associated air-flow. We present a coherent analysis of winds and waves from data collected during the ONR HiReS program from R/P FLIP off California, and from the Kvitebjorn platform in the Norwegian Sea. One aspect of these experiments is the strong conditions encountered with wind speeds up to 25m/s and significant wave heights up to 11m. A suite of wind and wave measuring systems were deployed allowing the resolution of the modulation of the wind by the waves. In particular, wave- and wind-scanning LIDARs ensured non-intrusive space-time measurements of the dynamics and kinematics of the MABL. We examine the effect of the statistical and deterministic properties of the wind and wave fields on the momentum fluxes and on the vertical and horizontal profiles of the wind velocity. COMPARISON BETWEEN SILICON AND NITRATE ISOTOPE RATIOS IN THE UPWELLING AREA OFF PERU

In this study we present the first direct comparison between dissolved stable silicon (δ30Si(OH)₄) and nitrogen (δ15N) isotopes in the upwelling area off Peru to investigate biogeochemical processes and nutrient cycling in one of the globally largest Oxygen Minimum Zones (OMZ). Silicon and nitrogen isotopes in the euphotic zone of the open ocean are mainly influenced by utilization in the way that diatoms preferentially incorporate the lighter isotopes, whereas in regions with prevailing anoxic waters the nitrate isotope composition is also altered by other processes. Silicic acid limitation offshore is indicated by high δ15N-Si(OH)₄ ratios (~15) leading to the highest δ30Si(OH)₄ values (3.7‰) accompanied by high δ15N-N₂ values (16‰). Due to upwelling and intense recycling of silicic acid on the shelf, surface samples show low δ30Si(OH)₄ values around 2‰. Nitrate isotope compositions in surface waters differ from values expected from δ30Si(OH)₄ suggesting that either N-loss (denitrification and/

MICROBIAL COMMUNITY DISTRIBUTION IN METHANE-BEARING SEDIMENTS FROM THE ULLEUNG BASIN
Microbial communities present in methane-bearing sediments from the Ulleung Basin were examined using FISH chip microarray analysis. Non-metric multidimensional scaling (NMS) and multi-response permutation procedures (MRPP) were used to determine whether microbial community compositions were significantly different according to whether communities were found in sulfate-methane transition zone (SMTZ) sediments, gas hydrate occurrence zone (GHOZ) sediments, or bottom-simulating reflector (BSR) sediments, and to correlate samples with abiotic characteristics of the sediments. This analysis indicated that communities from each zone were distinct from one another, and that depth, sulfate concentration, and alkalinity were the abiotic variables most correlated to the axis separating communities from each zone. In addition, two distinct community groups were found within the GHOZ; this may be explained by the proximity of certain communities to methane hydrate-bearing sediments. SMTZ communities were distinct between coring sites; this distinction is correlated with sediment concentrations of barium and manganese. These results suggest that microbial community composition in the Ulleung Basin may be determined by the presence of sulfate in the SMTZ and the proximity of communities to methane hydrate in the GHOZ. (Abstract ID 10320)
NOAA's Test and Evaluation of Conductivity/Temperature Sensors for Monitoring Salinity at Long Term Coastal Observatories

NOAA's Center for Operational Oceanographic Products and Services (CO-OPS) maintains a suite of conductivity/temperature (CT) sensors on a select number of its National Water Level Observation Network (NWLON) and Physical Oceanographic Real-Time System (PORTS) stations. All CT sensors currently in operation at these stations are manufactured by Falmouth Scientific, Inc. (FSI). In a continued effort to explore evolving technology, and to expand the arsenal of instruments available for operational use in CO-OPS observatories, the Greenspan EC3000 CT sensor was selected for test and evaluation. A series of laboratory tests was conducted in which both brands of sensor were compared against conductivity calibration standard solutions, then tested concurrently in CO-OPS seawater test bath facility. In two separate field tests, Greenspan sensors were compared to an operational FSI sensor at an NWLON station, and to a Sea-Bird SBE-32 on a NOAA Chesapeake Bay Intertidal Buoy System (CIBS) platform. A summary of laboratory and field tests will be presented, preliminary analysis of which indicates that the Greenspan EC3000 CT sensor compares favorably to the FSI CT sensor. (Abstract ID 12046)

Benthic Carbon Cycling in the Chukchi Sea: Status and Trends in a Changing Ecosystem

Sea ice retreat in the Chukchi Sea influences the timing and extent of organic carbon production and subsequent export to the underlying sediments. Multiple national and international studies in the Chukchi Sea over the last decade have investigated pelagic-benthic coupling, benthic carbon cycling and macrofaunal community composition and biomass. The northern Chukchi Sea is characterized by heterogenous sediments and more diverse benthic communities relative to the southern Chukchi Sea. High concentrations of surface sediment chlorophyll a and total organic carbon, along with high rates of sediment oxygen demand indicate relatively high export of organic carbon to the benthos in offshore waters of the SE Chukchi Sea, northern Chukchi Sea and in upper Barrow Canyon. By comparison, lower values of these parameters occur in nearshore Alaska coastal waters and the central offshore Chukchi Sea. Statistical analyses indicate that water mass type, depth, sediment grain size and food quality are the most significant variables driving benthic macrofaunal abundance and biomass. These findings will be discussed in relation to the international Distributed Biological Observatory effort to track biological response to this changing ecosystem. (Abstract ID 12580)

The Evolving Science of Ecosystem Modeling in the Gulf of Mexico: From Circulation to Populations

An integrated approach to the modeling of marine ecosystems requires consideration of biogeochemical processes, food-web interactions, and physical forcing mechanisms. Over the last 30 years, circulation and ecosystem concepts and observational and modeling programs have evolved in the Gulf of Mexico (U.S. and Mexican waters) with a steady convergence toward synergy. The majority of circulation models applied to the Gulf presently, generally do well in simulating Loop Current intrusion-separation cycles, eddy propagation, flow patterns through the Yucatan Channel, and deep cyclones under the Loop Current. However, there are unsettled issues, such as with modeling deep flows below ~1,000 m and the mechanism of energy transfer to the deep Gulf. Regional ecosystem models that couple 3D physical fields with biogeochemical processes (e.g., nutrient-phytoplankton-zooplankton-detritus, NPZD, or Lagrangian particle models) are in various states of development in the Gulf. A coordinated and integrated effort is required to build basin-wide ecosystem models that can address key questions, including variability in nutrient and gas fluxes, larval transport pathways, vertical organic matter flux, and ecosystem response to perturbations (e.g., storms, oil spills, climate variability, etc.). (Abstract ID 11398)
Eliciting linkages between human activity and coastal processes are paramount to estuarine preservation and management. For example, land use patterns can profoundly influence nutrient loading, primary productivity, and overall trophic status. This contribution summarizes results from a 3-year study (2008-2011) examining the effects of land use patterns on phytoplankton growth, community composition, biogeochemical cycling, and water quality within the Ashepoo-Combahee-Edisto (ACE) Basin (South Carolina, USA). A combined field and experimental approach was used. This included seasonal surveys of physical parameters, nutrients, phytoplankton, and bacterial indicators from several systems within the ACE Basin representing multiple land uses (forest, agriculture, agriculture, residences, waterfowl impoundments, and others). Seasonal in situ nutrient addition bioassays were performed over a two-year period (2009-2011), and both field and experimental results suggested a limitation of inorganic-N relative to it. Organic nutrients were likely the key drivers of overall productivity. In addition, correlations were found between water quality, nutrient levels, phytoplankton, and bacteria with land usage. Finally, evidence suggests that local hydrography may play an important role in the distribution of bacteria within the water column. (Abstract ID 11646)

SMALL SCALE CHANGES IN GELATINOUS ZOOPLANKTON COMMUNITY DURING UPWELLING AND RELAXATION EVENTS

Gelatinous zooplankton represent a poorly understood component of marine food webs in part because of difficulties estimating abundance using traditional net sampling techniques. The degree of vertical patchiness can influence the trophic impact of jellies, and the biophysical part because of difficulties estimating abundance using traditional net sampling techniques. During recent observations to understand how the internal tide propagates through Monterey Bay, CA, we found that sampling began at the end of a 12 d stretch of upwelling favorable winds. The first day of sampling was marked by a thin layer of high chlorophyll fluorescence and intense water column density stratification, with jellies, including large (> 8 cm bell diameter) scyphomedusae, most abundant at the strongest vertical density gradient. Subsequent sampling days were characterized by decreasing chlorophyll fluorescence and reduced water column density stratification, along with an abundance of Pleurobrachia spp. and the hydromedusa Eutonina indicans. Surface-associated thin layers of copepods occurred during and after the relaxation event. These layers were surprisingly devoid of gelatinous zooplankton and did not overlap spatially with the subsurface chlorophyll layer. (Abstract ID 10868)

MIXING AND FLOW IN ASCENSION, A STEEP NARROW CANYON

During recent observations to understand how the internal tide propagates through Monterey Canyon, we took limited measurements in nearby Ascension Canyon. Short, narrow, and straight, Ascension is opposite to Monterey in its physical characteristics, and there is no apparent internal tidal flux being steered by bathymetry into the canyon. Nevertheless, turbulence was only slightly less than in Monterey, and diapycnal diffusivity was larger, owing to weaker stratification. In addition to evidence of internal tides, mixing appeared to be also generated by flow along the continental slope dipping into the canyon. (Abstract ID 9314)

MODELING AND ASSIMILATING OCEAN COLOR RADIANCES

Radiances are the source of information from ocean color sensors to produce estimates of biological and geochemical constituents. They potentially provide information on various other aspects of global biological and chemical systems, and there is considerable work involved in deriving new information from these signals. Each derived product, however, contains errors that are derived from the application of the radiances, above and beyond the radiance errors. A global biogeochemical model with an explicit spectral radiative transfer model is used to investigate the potential of assimilating radiances. The results indicate gaps in our understanding of radiative processes in the oceans and their relationships with biogeochemical variables. Most important, detritus optical properties are not well characterized and produce important effects of the simulated radiances. Specifically, there does not appear to be a relationship between detrital biomass and its optical properties, as there is for chlorophyll. Approximations are necessary to get beyond this problem. In this report we will discuss the challenges in modeling and assimilation water-leaving radiances and the prospects for improving our understanding of biogeochemical process by utilizing these signals. DO WARM YEARS PROMOTE GREATER GROWTH AND SURVIVAL OF LARVAL COD ON GEORGES BANK?

A major shift in the zooplankton community on Georges Bank observed between the 1980s and 1990s has implications for the recruitment of marine fish. Warmer years promoted earlier spring blooms and the production of zooplankton prey for larval cod (Gadus morhua) across the Georges Bank region. Average daily growth was estimated by applying a static grid of stations at 10x10 km resolution covering the Georges Bank region. The larvae were constrained vertically at the thermocline at 20 m depth. Larvae were able to feed and grow through the day using bi-monthly observations of zooplankton and temperature observations as input to the IBM. Growth patterns were estimated for January-February, March-April, and May-June for the years 1977-2006. Extreme cold and warm years were identified and compared to address variation in growth rates related to annual and inter-annual variation in zooplankton and temperature conditions. Warmer temperatures and higher prey abundance promote higher potential growth and survival, an important component of recruitment. (Abstract ID 12403)

USING TOWED SENSOR OBSERVATIONS TO MODEL THE DISTRIBUTIONS OF TOTAL SUSPENDED SOLIDS IN HUMBOLDT BAY, CALIFORNIA DURING THE SPRING-SUMMER TRANSITION

End-member mixing models of bay and estuarine ecosystems are often used to predict temporal and spatial variations in sediments distribution and water chemistry. In Humboldt Bay, CA the factors controlling sediment and water chemistry are not currently understood to the degree required to develop appropriate mixing models. Here we present recent observations on two time series of suspended sediment distribution. A CDI with attached transmissometer was towed through the bay during three tidal conditions. Sensors collected TSS concentration, temperature, salinity, fluorescence and dissolved oxygen concentration. Data suggest that TSS is strongly sensitive to a threshold current velocity but that hydrographic and chemical parameters are not correlated to tidal data. Parameter distributions seem to result from mixing between two or three, variable end members that change significantly over the course of the spring-summer transition. Tow data and ancillary results from concurrently collected bay transects are used in constructing a complex mixing model that better explains observed trends and may also assist with the predictions of Humboldt Bay sediments distribution and water chemistry. DOPPELMEASUREMENTS OF TURBULENT KINETIC ENERGY DISSIPATION RATES NEAR THE OCEAN SURFACE

Turbulent Kinetic Energy dissipation rates (TKEDR) were obtained in the Labrador Sea during summer 2004, with instrumentation on an ASIS buoy equipped with meteorological...
and oceanographic sensors. The novelty of this data set consists in being obtained in the open ocean, and during a phytoplankton bloom. Using a coherent pulse-to-pulse Doppler sonar we obtained velocity fluctuation measurements at 150 densely spaced (0.8 cm) range bins, allowing us to calculate wavenumber spectra. The TKEDR were then calculated by means of the Kolmogorov theory, avoiding the use of Taylor's hypothesis. The analysis of these TKEDR in different wind regimes confirmed the fundamental role of wave effects together with the wind, as an essential factor to parameterize the TKEDR. Near surface TKEDRs were found to be enhanced above classical low-of-the-wall estimates at moderate to high wind speeds, and also to be independent of the wave phase, even at high winds. This is contrary to recent observations showing TKEDR beneath wave crests to be significantly enhanced over those beneath wave troughs, and helps resolve a recent controversy in the literature. (Abstract ID 10550)

GLOBAL AND LOCAL MODELING OF INTERNAL AND BAROTROPIC TIDES

As barotropic tides flow over submarine topography, internal tides are generated in the density-stratified ocean interior. These internal tides lead to an important energy transfer from the barotropic tide to the ocean interior, and play a role in determining barotropic tidal amplitudes on a global scale. Here, high-resolution numerical modeling is used to understand and quantify these processes. A linear internal tide generation model, valid for flow over large amplitude topography, is solved on a set of patches covering the entire ocean, using prescribed barotropic forcing and realistic continuous stratification. The implied global multi-constituent estimates of the associated energy transfer from the barotropic tide are consistent with observationally derived estimates. When these local models are coupled to a lower resolution global model of the barotropic tide, one obtains a global model of barotropic and internal tides, with no data assimilation or parameterized internal tide drag. These solutions are found efficiently by working in the frequency domain (rather than time-stepping the equations of motion), via direct inversion of large sparse matrices. (Abstract ID 11535)

SEX-SPECIFIC ZOOPLANKTON PHENOLOGY, PROTANDROUS DIAPAUSE EMERGENCE AND MIGRATION IN CALANUS SP.

Sex-specific life history strategies are an important but poorly researched area of copepod biology. Here we report on a literature study and subsequent analyses of two such strategies in Calanus: protandrous diapause emergence and protandrous migration. Abundance data were collected from the literature for males and females Calanus finmarchicus, C. glacialis, C. hyperboreus and C. helgolandicus across their distributions. Data were used to measure a) the time gap between peak male and peak female abundance, and b) the relative vertical distributions of the sexes around the reproductive season. Across all species, the date of peak male abundance preceded that of females in 90 of 105 discrete time series. We observed differences in the degree of protandrous emergence between species. Protandrous emergence may be advantageous to males in ensuring that they are ready to mate before female arrival. This study opens up a line of enquiry to a mostly unexplored area of zooplankton science. A focus on sex-specific phenotype is needed to improve our understanding of Calanus population dynamics and to predict how this important zooplankton group may respond to climate change. (Abstract ID 10797)

Grzić, J., University of Delaware, Lewes, USA, slgrim@udel.edu

LINKING ACTIVITY AND COMMUNITY STRUCTURE OF BACTERIAL ASSEMBLAGES IN THE SARGASSO SEA AND MID-ATLANTIC BIGHT

In this study we evaluated the relationship between abundance and activity levels of marine bacterial communities. Activity of microbial communities from the Mid-Atlantic Bight and Sargasso Sea in spring and summer over two years was assessed using 5-bromo-2’-deoxyuridine (BrdU) incorporation into synthesized DNA. Phylogenetic profiles of active (BrdU-labeled) and total (untreated) bacterial populations were obtained with 454 tag pyrosequencing, and statistical tests were conducted on relative abundance and activity levels. In both environments, a majority of observed bacterial groups were as active as expected based on their abundances. However, 2% of all bacterial groups in each environment had significantly different activity levels than abundances would indicate. In 80% of the communities, the rare bacterial fraction (1% or less of the total community) was more active than abundances would indicate. Additionally, the abundant bacterial fraction (5% or more of the total community) was less active than expected in 85% of the communities. By profiling differential activity levels of bacterial taxa, this study provided insight into the complex linkage between community structure and activity of bacterial assemblages. (Abstract ID 10566)
OCEANIC MEAN FLOWS FORCED BY TOPOGRAPHICALLY GENERATED INTERNAL WAVES

Generation of large-scale flows by dissipative internal waves as the main manifestation of wave drag is a well-known fact in atmospheric dynamics. However, it has been harder to apply to the ocean due to more complicated basin shapes or the random nature of the forcing. Unfortunately, our knowledge of the ocean circulation depends on such processes, namely internal wave generation, propagation and dissipation that global numerical models can’t resolve. In order to motivate future oceanic wave drag parametrizations, we propose to model balanced analytically balanced flows arising from the dissipation of topographically-generated internal waves. In a three-dimensional domain with constant buoyancy and Coriolis frequencies, a linear model for the radiation of dissipative Boussinesq waves by a barotropic tide flowing over small-amplitude topography is first derived. A non-linear forcing term acting on the phase-averaged vorticity equation is next derived using a generalized Lagrangian mean approach. This forcing resonates with the balanced mode, which then grows in time. Finally, important qualitative differences between rectilinear and rotary tides, as well as between various shapes of topographies, are highlighted. (Abstract ID 12431)

LOCAL GENERATION OF INTERNAL SOLITARY WAVES IN A PYCNOCLINE

Oceanic observations have provided evidence of the generation of internal solitary waves due to a tidal internal barb impinging on a seasonal pycnocline from below. The purpose of this talk is to present direct numerical simulations of such a generation process with the fully nonlinear and non-hydrostatic MIT-gcm model. An academic two-dimensional configuration in a vertical plane is first considered. We shall show that, depending on the parameters, different modes of internal solitary waves can be excited in the pycnocline and we shall provide examples of internal solitary waves as first, second and third modes, trapped in the pycnocline. The mechanism for the generation of internal solitary waves will then be put forward. This mechanism relies upon the matching of the horizontal phase speeds of the incoming wave beam and of an excited interface wave trapped in the thermocline. Application to the Bay of Biscay will then be considered. (Abstract ID 12265)

TROPICAL ATLANTIC INSTABILITIES IN CCSM4

We focus on the tropical Atlantic instabilities in the 20-th century CCSM4 run. The biases appear in both atmospheric and oceanic components. Mean sea level pressure (MSLP) is too high by a few mbar in the sub-tropical highs and too low in the polar lows. As a result, surface winds in the tropics are ~1ms/s too strong that causes excess evaporation and depressed SSTs north of the equator. However, south of the equator SST is too warm due to the evaporative cooling being outweighed by the warming by other factors. The highest SST bias is close to the coast Biscay will then be considered. (Abstract ID 12426)

ECOLOGICAL RISKS OF ANTHROPOGENIC NOISE ON FRESHWATER FISHERY RESOURCES

With the rise in global demand for natural resources, the development, exploration, and extraction using new and traditional energy technologies in the United States is a priority. With recently discovered regions of oil and gas reserves from inland sources, particularly throughout the upper Missouri River basin, there has been increased interest in surveying freshwater ecosystems such as lakes and riverbeds. In accessing these new resources it is critical to better identify the ecological ramifications of expanding traditional methods into new environments as significant challenges may be placed on ecological patterns and distributions of fishery resources not present in the marine environment. Of growing concern are the effects of anthropogenic noise on fishes. Research on the effects of anthropogenic noise has primarily been directed at mitigating impacts to marine mammals while few peer-reviewed studies characterize the effects of these noise sources on fishes. This presentation will discuss the risks of increased use of seismic air guns, piling driving, and wind farms to fishery resources. (Abstract ID 12426)

SHIFT IN NUTRIENT LIMITATION AFFECTS BIOCHEMICAL COMPOSITION OF NORTH SEA PHYTOPLANKTON

Coastal waters of the North Sea have been affected by eutrophication over the past decades and subsequent efforts to reduce nitrogen nutrient loads resulted in a major shift in N/P Si nutrient ratios. The consequent changes in the limiting resource can alter the biochemical composition of phytoplankton. As phytoplankton presents the base of the food web, its biochemical composition also affects the structure and functioning of food webs and subsequently the carrying capacity of the ecosystem. Novel approaches using liquid chromatography and gas chromatography in combination with isotope ratio mass spectrometry make it possible to trace stable isotope incorporation into major cellular components such as carbohydrates, amino acids and fatty acids. The work presented here investigates synthesis rates of these different understanding of the diffusive and advective processes that contribute to the modification of water masses and the MOC is needed. The vertical mixing coefficient, D, and along-isopycnal mixing coefficient, K, is thought to strongly control the MOC and climate sensitivity. Inverse methods are tools used to diagnose the ocean circulation from hydrographic data. Inverse models have so far, been unable to resolve the spatial structure of D and K. Recently an over-determined tracer-contour Inverse Method (TCIM) is established, which is less sensitive to error than existing inverse methods and has the potential to resolve the magnitude and vertical distribution of D, K, and the geostrophic flow directly from hydrographic data. Recent progress on the TCIM now allow for multiple ‘communicating’ boxes. This, and replacing K with simply the isopycnal heat flux (from which K can be determined), is expected to increase accuracy of the TCIM and finally allow for a ‘global inversion’ resulting in a global spatial distribution of K, D and the geostrophic flow. (Abstract ID 9811)
biochemical components in natural phytoplankton communities of the North Sea and in cultures grown under different nutrient limitations. Though still preliminary, this work will make it possible to infer changes in phytoplankton stoichiometry and consequent food web changes based on knowledge of prevailing resource conditions. DEMESIAL FISH ASSEMBLAGES ASSOCIATED WITH DESOTO CANYON AND THE CONTINENTAL SLOSE OF THE EASTERN GULF OF MEXICO RELATIVE TO THE DEEWPWATER HORIZON OIL SPILL

Edge habitats typically have high biodiversity and biomass regardless of ecosystem, but such deep-sea habitats (e.g. continental slopes, submarine canyons, seamounts) remain relatively unexplored. DeSoto Canyon and adjacent continental slope habitats of the eastern Gulf of Mexico were the first affected by the Deepwater Horizon oil spill (DWH). Deep-water fishes have slow life histories and are among the most sensitive taxa to environmental perturbations yet in the Gulf of Mexico these taxa are poorly documented, many taxonomies are unresolved and new species undoubtedly exist. We used fishery-independent longline and trap surveys to describe the deep-water assemblages of large demersal fishes in this region. We also examined dominant species for exposure to polycyclic aromatic hydrocarbons (PAHs), petroleum-derived toxins that may affect fish health. During 2011, 73 stations (199-2,014 m deep) yielded 626 fishes including two species of hagfishes, 15 species of elasmobranchs and 21 species of teleosts. Fish assemblages and abundances were similar among regions and mediated by depth and temperature (85%) were captured <600 m deep). Detected exposure to PAHs was a function of proximity to the DWH site. (Abstract ID 12271)

OCEAN DEOXYGENATION - STATUS AND TRENDS

Theoretical consideration as well as ocean biogeochemistry models robustly predict that global warming will lead to a substantial decrease in the ocean’s oxygen content. The main drivers of this ocean deoxygenation are well understood, i.e., reduced solubility of oxygen in seawater and increased stratification, but the spatial distribution of the expected changes in oxygen as well as the potential impact of these changes are not well established. Few places exist that not only permit the estimation of long-term trends, but also allow for a proper assessment of such trends against shorter-term variability. Notable exceptions are the North Atlantic and the North Pacific, where the data to date suggest a complex pattern of changes that likely reflect as much (natural) climate vacillations as it represents a response to (anthropogenic) ocean warming. Even weaker is our current ability to understand and model the impact of ocean deoxygenation on open ocean regions with hypoxic or even anoxic conditions. In this presentation, the current status in our understanding will be reviewed and recent trends discussed. (Abstract ID 11085)

TOWARD A GLOBAL DATA-BASED ESTIMATE OF THE OCEANIC ACCUMULATION OF ANTHROPOGENIC CO2 SINCE THE WOCE ERA

Model simulation predict that the ocean has accumulated approximately 20 to 30 Pg C between the WOCE era (mid-1990) and the CLIVAR era (mid-2000), which represents roughly a 20% increase in the amount of anthropogenic CO2 stored in the ocean. In the last decade, a series of repeat hydrographic cruises have been undertaken with the goal to document and quantify this accumulation. More recently, international synthesis activities have quality controlled and homogenized the data on a basin-scale, opening the opportunity to estimate the anthropogenic CO2 accumulation in the ocean since the WOCE era with a high-quality data set. We will report on our first attempts to estimate this increase on a global-scale, using a range of methods, including the eMLR, ΔTIce, isoprell ΔCT0, and TTD methods. This will permit us to assess the uncertainties associated with the separation of the changes in total inorganic carbon from those associated with the uptake of anthropogenic CO2. We will also address the challenges associated with the temporal and spatial interpolation required to arrive at a global integrated number given the relatively sparse data sets. Good knowledge of the global oceanic uptake of anthropogenic CO2 between the mid-1990s and the mid-2000s will provide much needed constraints for the global carbon budget over this period. MACROFAUNAL COLONIZATION AND TROPHIC DYNAMICS AT TWO EAST PACIFIC METHANE SEEPES (HYDRATE RIDGE AND COSTA RICA)

Methane seeps, including those at Hydrate Ridge on the Cascadia margin and Mound 12 off Costa Rica, are characterized by diverse microbial consortia that fix inorganic carbon and precipitate authigenic carbonates. By placing results of in situ substrate colonization experiments and ex situ isotopic tracer experiments within an isotopically-defined food web, we were able to test the hypothesis that fluid flow and substrate type and availability structure communities at deep-sea methane seeps. Fluid flow was more important than substrate type in defining communities, except for a few substrate specialists (e.g. Xyloplax on wood). Though 10- and 13-month deployments were insufficient for community recovery, macrofaunal densities and biomass were higher on substrates placed in active seepage, while taxonomic richness was greater at inactive reference sites. Similar taxa characterized substrates in areas of active seepage at sites separated by 6000km (e.g. ampharetid and dorvilleid polychaetes, the gastropods Proswana laevis and Pyrgopelta coronula). Stable isotopic ratios suggest a dependence on multiple chemosynthetic pathways in both active and inactive settings, and tracer experiments identified specific metabolic pathways that contribute carbon and nitrogen to macrofauna. COST-MINIMIZATION STRATEGIES OF MARINE MICROBES AND THEIR POTENTIAL IMPACTS ON NP CYCLING IN THE UPPER OCEAN

High throughput sequencing increased our ability to resolve distributions and functions of marine microbes. While diversity of microbes found in any one sample can be staggering a few phytophyle types consistently dominate communities in oligotrophic oceans. Recent work reports that high-latitude oceans and the mesopelagic ocean support chemolithotrophic sulfur and ammonia oxidation in diverse lines of bacteria and marine group I archaea. The impacts of these processes on the global carbon and nitrogen cycles are only beginning to be detailed. Based on analyses of nitrogen requirements of dominant oligotrophic microorganisms and their potential for non-Redfield C:N:P stoichiometry we hypothesized that deviations from Redfield N:P in areas of the surface ocean not dominated by nitrogen fixation can be explained by impacts these highly optimized microorganisms have on inorganic N dynamics. In the Southern Ocean, for example, positive N values observed in the upper ocean cannot adequately be explained by nitrogen fixation nor advecive processes. In these waters 15-30% of surface ocean microbes have the potential to perform nitratification during winter. Using a simplified box model we show the impact these organisms and their vertical distribution have on surface ocean N:P ratios. We hypothesize that in the modern ocean, over geologic time scales, biogeochemical processes occurring in the surface ocean will favor organisms that are cost minimized for nitrogen and iron. IN SITU MEASUREMENTS OF SKIN SST FOR SATELLITE SST CLIMATE DATA RECORD

Sea Surface Temperature (SST) is an essential indicator for climate change. High accuracy and stability of the satellite SST products are required for long-term climate data record of global SST. It is important to routinely collect in situ SST measurements for the evaluation and improvement of the quality of satellite SST products. The infrared SST autonomous radiometer (ISAR), made by the University of Southampton, has been deployed on the research vessel Dong Fang Hong II of Ocean University of China since September 2009. The R/V Dong Fang Hong II operates mainly in the China Seas including Bohai Sea, the Yellow Sea, the East China Sea and the South China Sea, for about 300 days per year. The ISAR was installed on the top of the research vessel, around 13 m above the sea surface. The skin SST measurements were collected during eighteen cruises in this area from 2009 to 2011. These in situ SST products are compared with shipboard measurements of skin SST. The results will be presented and
discussed. (Abstract ID 10153)

Guerra, G. E., University of Florida, Gainesville, USA, gisselle.guerra@ufl.edu

This study investigates the relationship between the South China Sea summer monsoon and the first tropical cyclone (TC) of the season to make landfall over mainland China (in short, the first-landfall TC) using the South China Sea summer monsoon index, NCEP/NCAR reanalysis monthly average data, and best-track TC data from Joint Typhoon Warning Center (JTWC) for 1948–2009. The results show that the characteristics of the first-landfall TC are closely associated with the frequency, active stage, and strength of subsequent landfall TCs in the same year. In detail, a stronger (weaker) South China Sea summer monsoon index year corresponds to more (fewer) landfall TCs over Mainland China, a later (earlier) date of the first-landfall TC, a lower (higher)-latitude landing point of the first-landfall TC, and a stronger (weaker) monsoon trough. The anomalous wind field and the track of the first-landfall TC are also significantly related to the strength of the index. The location of the first-landfall TC has shown a gradual trend toward higher latitudes over the analysis period, and there is a decreasing trend in the variability of the South China Sea summer monsoon index. (Abstract ID 9462)

Guinasso, N. L., Texas A&M University, College Station, USA, guinasso@tamu.edu

THE FIRST-LANDFALL TROPICAL CYCLONE OVER MAINLAND CHINA

The North Atlantic Ocean is an important oceanic region with a high variability in tropical cyclone formation and development. Understanding the factors that influence the first-landfall TC over mainland China is crucial for improving hindcast and short-term forecasts of TCs. This study investigates the relationship between the South China Sea summer monsoon and the first-landfall TC over mainland China using NCEP/NCAR reanalysis monthly average data and best-track TC data from JTWC for 1948–2009. The results show that the characteristics of the first-landfall TC are closely associated with the frequency, active stage, and strength of subsequent landfall TCs in the same year. In detail, a stronger (weaker) South China Sea summer monsoon index year corresponds to more (fewer) landfall TCs over Mainland China, a later (earlier) date of the first-landfall TC, a lower (higher)-latitude landing point of the first-landfall TC, and a stronger (weaker) monsoon trough. The anomalous wind field and the track of the first-landfall TC are also significantly related to the strength of the index. The location of the first-landfall TC has shown a gradual trend toward higher latitudes over the analysis period, and there is a decreasing trend in the variability of the South China Sea summer monsoon index. PRINCIPAL COMPONENT CHARACTERIZATION OF FLUORESCENCE SPECTRA FROM SEAWATER SAMPLES COLLECTED DURING THE DEEP WATER HORIZON OIL SPILL

In 2010 more than 300 water samples were taken in the deep waters of the Gulf of Mexico on
several cruises aboard the R/V Walton Smith (Joye et al. 2011) and R/V Pelican, and one cruise aboard the R/V Weatherbird. The first Pelican cruise in May 2010 collected samples in the sub-surface plume from the Deep Water Horizon incident (Diercks et al. 2010). Samples taken on the later Pelican and Weatherbird cruises in May and June of 2010 were taken in the Loop Current and its associated Warm Core Ring ( Wade et al. 2011a, 2011b). We report analysis of a combined excitation-emission data set by Principal Components Analysis (PCA). The scanning fluorometer produces a 31 by 31 matrix of excitation-emission values. The significant excitation emission values can be put into a linear vector with 237 values and assembled into a large matrix with each row representing the 237 results from each sample. The matrix was decomposed into principal components and scores using standard methods. About 90 percent of the variance in the matrix can be explained by the first 5 principal components. Most samples in the plume have principal components are distinct from most samples taken in the loop current and ring. The plume samples have principal components similar to the NIST DWH standard oil and to the principal components of a surface oil slick sample collected during the spill. (Abstract ID 12138)

EXTREME TURBULENT HEAT FLUXES IN WESTERN BOUNDARY CURRENTS: A NEW FRAMEWORK FOR QUANTIFICATION AND ANALYSIS

We analyze the probability density distributions of surface turbulent heat fluxes, applying the two parametric modified Fisher–Tippett (MFT) to air–sea flux estimates derived from reanalyses state variables and from the Voluntary Observing Ship (VOS) data. Extreme turbulent heat fluxes amount to 1500–2000 W/m² (for the 99th percentile) and can exceed 2000 W/m² for higher percentiles in the western boundary current extension (WBCE) regions. Analysis of linear trends and interannual variability in the mean and extreme fluxes shows that the strongest trends in extreme fluxes (more than 15 W/m² per decade) in the western boundary current regions are associated with the changes in the shape of distribution. In many WBCE regions changes in extreme fluxes are different from those for the means at interannual and decadal time scales. In particular, the correlation between interannual variability of the mean and extreme fluxes is relatively in the Southern Ocean and the Kuroshio Extension region. Newly derived probability distributions have also been used in assessing the impact of sampling errors in the VOS-based surface fluxes. Although sampling does not have a visible systematic effect on mean fluxes including WBCE regions, sampling uncertainties may result in the strong underestimation of extreme flux values exceeding 100 W/m². New framework allowed to derive the requirements to the observational and modelling platforms for the successful replication of extreme turbulent fluxes. (Abstract ID 10378)

CRITICAL BEHAVIOR OF FLUID AND ELECTRICAL TRANSPORT IN SEA ICE

The fluid transport properties of sea ice mediate melt pond evolution and ice pack reflectance, snow–ice formation, nutrient replenishment for microbial communities, and the evolution of salinity profiles. Electromagnetic monitoring of these processes relies on some knowledge of the effective electrical properties of sea ice. Columnar sea ice is effectively impermeable to fluid flow below a 5% brine volume fraction, yet is permeable for brine volume fractions above this threshold value. In two different experiments conducted in the Arctic and Antarctic, we have found that this critical transition in fluid flow at the brine connectivity threshold displays a strong electrical signature, laying the foundation for electromagnetic monitoring of transport phenomena in sea ice. Here we also modify traditional percolation models for columnar sea ice, hypothesizing that granular sea ice has a percolation threshold near a 10% brine volume fraction. This modified percolation model is then in excellent agreement with our field data taken in Antarctica, where granular ice is a significant component of the ice cover. (Abstract ID 12882)

RIVER DISCHARGE, STRATIFICATION AND SHELF WATER HYPOXIA IN THE MISSISSIPPI BIGHT

Ecosystem metabolism, driven by available organic and inorganic nutrients, is an important end-point indicator for water quality and health of estuarine systems. When community consumption of dissolved oxygen (DO) exceeds the rate of production, hypoxia (<2mg DO/L) or even anoxia (no oxygen) may develop. Sources of inorganic and organic nutrients in estuaries are derived from rivers and terrestrial runoff. The regional summer stratification in the Mississippi Bight is strengthened by offshore advection of fresh surface waters and onshore advection of high density bottom waters. Our monthly Northern Gulf Institute (NGI-NOAA) surveys of the Mississippi Bight show that hypoxia is a regional phenomenon that can extend as far as 10m above bottom and last through the entire summer (4 months). In the fall, hypoxia is interrupted by episodic wind events (hurricanes) and vertical mixing will reintroduce DO to the bottom waters. Results from the 4-year monitoring program suggest that, in addition to tidal nutrient inputs, physical processes such as river discharge, advection, mixing, and air-sea interactions, exert important controls on the net outcome of DO in the ecosystem. REDOX CONTROL OF THE PARTITIONING AND SCAVENGING OF Fe(III) AND Pa(V ) IN SEAWATER: ROLE OF NATURAL ORGANIC MATTER

Controlled laboratory radiotracer experiments were carried out to examine the phase partitioning of Fe(III, III), Pa(V, IV) and Th(IV) in seawater in the presence or absence of macromolecular organic matter, including humic substances (HS) and exopolymers (EPS), and to examine the role of natural organic matter in controlling the biogeochemical cycling of trace elements. The partitioning of $^{55}$Fe, $^{233}$Pa and $^{234}$Th between dissolved, colloidal and particulate phases showed that while values of their particle- or colloid-water distribution coefficients (logKd or logKc) are consistently high (5.7-7.3), their colloidal size spectra and apparent solubilities were significantly different. The particle-reactivity followed the general order of Th(IV)>Fe(III)>Pa(V) in low DOM seawater, with the highest apparent solubility (~1 kDa) observed for Pa(V). In the presence of EPS or HA, however, the apparent solubility followed the order of Fe(III)>Th(IV), Pa(V). We hypothesize that, while the reactivity of Th(IV) remained unchanged, Fe(III) and Pa(V) can be reduced to Fe(II) and Pa(IV) by macromolecular organic matter on particulate surfaces, resulting in higher solubility for Fe(III) and promoting reductive scavenging of Pa(V) in marine environments. NUMERICAL STUDY OF THE INFLUENCE OF SURFACE WAVES ON TURBULENCE IN THE UPPER OCEAN

To understand the dynamics of the interaction between upper ocean turbulence and surface waves, we perform direct numerical simulation for turbulence in the presence of a progressive wave. The simulation provides an instantaneous, three-dimensional description of the flow field for a detailed examination of turbulence structure under the distortion of surface wave. The periodic and accumulative effects of the wave on the turbulence are studied in Eulerian and Lagrangian frames, respectively. In the Eulerian frame, turbulence is found to be wave-phase dependent. Turbulent vortices are turned, stretched, and compressed periodically, leading to a phase-dependent distribution of enstrophy. The variation of Reynolds normal stress is explained by the analysis of their budget. In the Lagrangian frame, the wave dissipation due to wave-turbulence interaction is quantified through the Reynolds shear stress and the Lagrangian property of the wave. Vertical vortices are shown to tilt towards the wave propagation direction due to both the Stokes drift and the correlation between wave strain rate and turbulence vorticity, which yields a potential mechanism for the initial development of small-scale Langmuir cells. DETERMINATION OF THE OCEAN INTERNAL WAVE PROPERTIES FROM NAUTICAL X-BAND RADAR OBSERVATIONS

Nautical X-Band radar is generally equipped on ship for navigation purposes. It can detect the sea surface roughness with high temporal and spatial resolution. In this paper, an approach is proposed to retrieve the properties of ocean internal wave from ship-borne X-band radar observations. First of all, the nonlinear velocity of internal wave is derived from radar images based on R adon Transform technique. The second, given the vertical distributions of backscattering data, the Thomson-Haskell method is used to solve the Taylor-Golstein boundary value problem (eigenvalue problem). Then, the amplitude of internal soliton can be retrieved from the data acquired in June 2009 in the South China Sea based on the Korteweg-de Vries (KdV) equation for continuous stratified finite depth system. The retrieval amplitudes are consistent with these observed by towed thermistor chain. Finally, the uncertainty of the method is also discussed. (Abstract ID 9502)

MIXING IN THE CENTRAL ARCTIC OCEAN IN RECENT YEARS

Since 2007, the North Pole Environmental Observatory has launched expendable current probes (XCP) as part of annual springtime airborne hydrographic surveys in the central Arctic Ocean. Mixing is estimated from 10-meter shear and CTD-derived Brunt-Väisälä frequency for comparison with Arctic Ocean mixing in the 1980’s estimated using the same method. Mixing estimates from simultaneous XCP and microstructure profiles provide consistent results. The present, survey-averaged mixing estimates for the deep Arctic Ocean are an order of magnitude higher than those found during the 1980s. Our observations have mainly been made under a complete springtime ice cover, so the decline in ice extent is not the cause of the mixing increase. Possible explanations include increased near-inertial ice motion due to decreases in thickness and enhanced generation associated with changes in circulation and stratification. One 2008 CTD-XCP station over the Lomonosov Ridge is intriguing in the latter regard. It suggests a significant eddy-like feature in the Atlantic Water layer with abnormally high temperatures and several well-mixed layers 50-100 meters thick. The XCP data indicate high mixing rates below this feature. (Abstract ID 10548)

MOLECULAR AND ECOLOGICAL DIVERSITY OF PICOCYANOBACTERIAL POPULATIONS IN THE COSTA RICA DOME

The Costa Rica Dome (CRD) is an offshore mesoscale feature that develops seasonally in the eastern Tropical Pacific. Despite its upwelling nature, picocyanobacterial populations dominate the surface mixed layer. The present study investigated the abundance and diversity of Synechococcus and Prochlorococcus across the nutrient-rich CRD and surrounding oligotrophic waters. Depth-resolved sampling for flow cytometry and DNA analysis of picocyanobacteria assemblages was accompanied by physico-chemical characterization of the water masses harboring them. Phylogenetic analysis based on the rpoC1 gene marker revealed various populations of Synechococcus and Prochlorococcus with different distributional patterns. Most of the Synechococcus-like sequences from surface waters fell into one cluster with no closely related known isolates, while a few sequences clustered together with Synechococcus Clade II. Cytoskeletal composition shifted dramatically below the mixed layer. Most of the sequences within the dome were closely related to Prochlorococcus MIT9303 and MIT9313 and were distinct from Prochlorococcus sequences outside, which were more similar to the NATL2 isolate. Overall, we observed a strong shift in community composition above and below the pycnocline, while changes along the horizontal scale were less pronounced. (Abstract ID 12460)
results underline the nascent state of coccolithophore cell physiology and the importance of a mechanistic understanding of inter- and intraspecies sensitivity differences to predict future changes in calcification of natural coccolithophore assemblages. (Abstract ID 12019)

THE EFFECT ON RUNUP OF INCIDENT WAVE DIRECTIONAL AND FREQUENCY BANDWIDTH

Shoreline runup during storms is dominated by infragravity waves (periods ~ 100sec). Infragravity waves are driven by shoaling incident sea swell waves (periods ~ 10-sec), and are reflected partially at the shoreline. Observation-based empirical formulas suggest infragravity energy generally increases with increasing incident wave energy and period. However, runup observed and predicted (with these formulae) is scattered, suggesting other variables may be important. We investigate numerically the infragravity energy dependence on incident wave frequency and directional bandwidth. The numerical model, a phase-resolving Boussinesq formulation fumwaveC (similar to FUNWAVE and COULWAVE) simulates wave breaking at the front face of steep waves with an eddy viscosity term. Preliminary results show that, on a planar beach with normally incident waves with fixed energy and peak period, runup levels can differ substantially with varying directional and frequency bandwidths. The role of wave breaking and energy transfer to sea swell waves on infragravity energy levels is also investigated. (Abstract ID 9914)

COUPLED-OCEAN-ATMOSPHERE-WAVE MODELING OF WEATHER FRONTS

A five day nearshore field experiment in December 2003 near Myrtle Beach, SC, provided concurrent measurements of waves, currents and bathymetry within the surfzone and offshore inner shelf. To investigate the connection between nearshore, inner shelf and atmospheric processes that drive the coastal flows we use a newly developed Coupled Ocean – Atmosphere – Wave – Sediment Transport (COAWST) Modeling System using the Model Coupling Toolkit to exchange prognostic variables between the ocean model ROMS, atmosphere model WRF and wave model SWAN. The modeling system allows seamless resolution from the North Atlantic Ocean (regional scale) to the inner continental shelf to the surf zone (local scale). The first two weeks of December were simulated, including the passage of two weather fronts. The first storm generated waves from the south driving a moderate northerly longshore current. The second front generated waves with a large angle of incidence from the north, driving southerly longshore currents approaching 2m/s. Results from the model system are utilized to understand the connections between the large-scale weather patterns and the observed wind driven offshore and wave driven surfzone flows. (Abstract ID 10841)

IMPORTANCE OF MESOSCALE FEATURES IN THE GULF OF MEXICO ON LARVAL PELAGIC FISH ABUNDANCE

The management of fisheries requires accurate estimates of spawning stock biomass, preferably through the use of accurate fishery independent indices. Better understanding of environmental variables that influence larval distributions in the Gulf of Mexico will help improve fisheries-related indices. This research investigated whether larval abundance of a variety of pelagic fish species (Thunnus thynnus, Auxis spp., Euthynnus alletteratus, Katsuwonus pelamis, Coryphaena spp, Istiophorids, Other thunnus spp., and Xiphias gladius) collected during annual NOAA SEAMAP spring ichthyoplankton surveys in the Gulf of Mexico were related to mesoscale circulation features. Visual and automated methods of classifying the features were compared, and variability in larval abundances and species diversity was assessed using a variety of non-parametric multivariate statistics. COMPARISON OF DOPPLER- AND RADAR CROSS SECTION-BASED WAVE HEIGHT SPECTRA FOR LOW SEA STATES

Using radar as a remote sensing technique for measuring ocean surface waves presents several advantages over conventional point sensors. Although our understanding of the scatterers contributing to the backscattered signal as well as the methods used to extract wave field information from these signals have progressed over the last several decades, many questions still remain. Measurements of wave fields using dual-polarized high-resolution X-band pulse-Doppler radar at low grazing angles along with two independent measurements of the surface waves using conventional sensors were performed offshore of the Scripps Institution of Oceanography pier. These data were taken in low sea states so effects associated with breaking waves are minimized. Cross-correlation functions between radar cross section (RCS) and Doppler signals are used to contrast and characterize signal modulations in the spatiotemporal domain. Doppler and RCS measurements are also used to compute wave height spectra, and comparisons between them are examined for both vertical-transmit and vertical-receive, and horizontal-transmit and horizontal-receive polarizations. Wave height spectra and associated wave statistics computed from the conventional sensor data are compared with those obtained from the radar measurements. (Abstract ID 10385)

HUMAN INFLUENCES ON THE CHEMICAL COMPOSITION OF ORGANIC MATTER IN STREAMS AND LAKES OF THE HIMALAYAS

This study focused on quantifying human influences on the water systems of Nepal, specifically in the cities of Kathmandu and Pokhara, the Langtang Valley region and the Khumbu (Everest) region. Water samples were collected from surface sources and one well. Sampling sites were chosen for their proximity to local population and tourism centers. Solid phase extraction followed by gas chromatography time-of-flight (GC-TOF) mass spectrometry was used. Plasticizers were found to be some of the most abundant identifiable compounds in the samples. Diethylhexyl Phthalate (DEHP) was found in all (n=13) samples, with concentrations up to 5 ug/L. Diethylene Phthalate (DCHP) was found in most samples, with a concentration <170 ug/L. Dibutyl Phthalate (DBP) and Bisphenol A (BPA) were found in some samples. The highest concentrations DCHP and DBP were in samples taken in city regions. The highest concentrations of DEHP were also from city regions, but concentrations of more than half the maximum were also found in remote headwater regions. (Abstract ID 12436)

INFLUENCES OF HYDROTHERMAL PLUME FALLOUT AND MINERALOGY ON MICROBIAL COMMUNITIES: INSIGHTS FROM IN SITU EXPERIMENTS AT THE LOIHI SEAMOUNT, HAWAII

The Loihi Seamount is the newest volcano in the Hawaiian chain and is very hydrothermally active. The hydrothermal fluids are rich in iron and poor in H2S and offer the ideal environment to study biotic iron cycling. Polished panels of various iron-bearing minerals were placed at the seafloor near the hydrothermal vent and on the flanks of the Loihi Seamount for up to three years and upon retrieval, the panels were found to be colonized by microorganisms. The cells were enumerated via fluorescent microscopy and the communities were characterized via 16S Sanger sequencing. Here, we present preliminary results and discuss the implications for any mineralogical and hydrothermal influences on microbial communities. (Abstract ID 12627)

CLASSROOM CONNECTION: A SHIP-TO-SHORE INITIATIVE TO ENGAGE SPECIAL EDUCATION STUDENTS IN OCEANOGRAPHIC RESEARCH

In July - September 2010, scientists on board the research vessel JOIDES Resolution (the "JR")
during the Integrated Ocean Drilling Program (IODP) Expedition 327 interacted with one elementary ‘special education’ classroom in the Phoenix metro area via blogs and Q&A. The excitement and enthusiasm generated by this interaction inspired the “Classroom Connection” initiative, a 10 week ship-to-shore project aimed at teaching federally- and Arizona state- mandated curriculum standards using ship-to-classroom interaction. The project was implemented during IODP Expedition 336 (fall of 2011) and included hands-on classroom activities, web-based lessons, blogs, Q&A and an interview series with personnel on the JR.

Four elementary ‘special education’ and ‘special needs’ classrooms in the Phoenix metro area participated for all 10 weeks. We present the successes and challenges of this project and what implications they may have for ‘special education’ curriculum. (Abstract ID 12642)

CANNOT SOUTHERN OCEAN PROCESSES MAINTAIN STRATIFICATION, OVERTURNING, AND HEAT TRANSPORT IN AN OCEAN WITH AN ADIABATIC INTERIOR?

We use a novel Lagrangian ocean model to explore the role of Southern Ocean processes in maintaining ocean stratification, the meridional overturning circulation, and poleward heat transport in an ocean with an adiabatic interior. This model is perfectly suited for simulations in the limit of zero diffusivity, since it produces no spurious mixing, and it does not require the Gent-McWilliams parametrization to generate oceanic bolus transports. When our idealized zero-diffusion ocean with a circumpolar channel is exposed to a realistic zonal wind stress and surface density restoring, the resulting ocean stratification, meridional overturning and poleward heat transport resemble those observed in the Atlantic. We test sensitivities of these features to variations in key dynamical factors, including the depth of the circumpolar channel, the strength of northern and southern hemispheric westerlies, and the imposed density in the North. The deep overturning cell, the mid-depth stratification, and the northward penetration of Antarctic Intermediate Water depend strongly on the co-existence of the circumpolar channel, southern hemispheric westerlies and density surfaces that outcrop in both the channel region and the northern high-latitudes. REAL TIME MODELING AND OBSERVATIONS OF THE 2011 TSUNAMI DEBRIS FROM JAPAN

SCUD (Surface CURRENTs from Diagnostics) model is used to simulate motion of debris from the 11 March, 2011 tsunami in Japan. The SCUD utilizes near-real time AVISO altimetry data along with real-time ASCAT ocean surface winds to assess ocean surface currents, consistent with trajectories of drifting buoys, used in the Global Drifter Program. The result is a daily map of surface currents on 1/4 degree lat/long grid. These ocean surface current fields are applied to model the transport of tsunami debris. The debris is represented in the model by 678,000 tracers released on the day of tsunami near the east coast of Japan. The daily-updated maps of the debris field are public at http://iprc.soest.hawaii.edu/users/hafner/PU/SCUD/TSUNAMI_DEBRIS/tsunami_tracers_no_vector_large.html Reports on sightings of debris at sea ocean have been used to validate and improve the model. Practical applications of the modeled field of tsunami debris include the assistance for maritime safety and coordination of coastal clean-up operations. (Abstract ID 12648)

RESPONSES OF MONTASTRAEA FAVELOLATA CALCIFICATION, RESPIRATION AND PHOTOSYNTHESIS TO SEAWATER CHEMISTRY CHANGES SIMULATING THE EFFECTS OF OCEAN ACIDIFICATION

Zooxanthellate coral calcification rates (CR) are generally 2-4 times higher in the light than in the dark. Ocean acidification reduces seawater pH and has been documented to reduce coral CR, presumably because photosynthesis cannot raise the pH enough to overcome the negative effects of the decrease in seawater pH. We used a Tris buffer to stabilize seawater pH during incubations to measure coral CR under a range of pH values spanning pre-industrial to predicted 2100 values. Results show that at a Tris stabilized pH of 8.2 or 8.6, there was no difference between light and dark CR due to enhanced dark CR, while at pH 7.5 or 7.9, light CR was 2-fold that in the dark due to reduced dark CR. Respiration rates remained relatively constant over the pH range examined; however, photosynthetic rates tended to decrease with higher pH which resulted in a trend of lower P/R ratios with increasing pH. This may indicate a small stimulation of photosynthesis due to higher PCO2. Further experiments are examining the relationships of calcification, photosynthesis and respiration to seawater pH. TEMPORAL TRENDS OF BENTHIC FAUNA IN THE NORTHEASTERN CHUKCHI SEA, 2008-2010

An interdisciplinary study evaluated benthic communities near three proposed oil and gas exploration areas (Burger, Klaudtik, and Statoil) in the northeastern Chukchi Sea annually in 2008-2010. This study was sponsored by ConocoPhillips, Shell Exploration and Production Company, and Statoil USA E & P to collect biological and environmental information in these areas prior to exploration and provide data useful for permit applications and post- exploration comparisons. Benthic macrofauna and megafauna populations were surveyed and trends in abundance and biomass analyzed. Dominant benthic taxa exhibited temporal trends associated with oceanographic conditions that reflected climate variability. Macrofaunal abundance and the number of taxa increased with higher water temperatures and declined with colder temperatures while megafaunal responses were less clear. While trends were associated with water temperature, variations were found for both macrofauna and megafauna. Individual taxa responded to the inter-annual variability of oceanographic conditions to varying degrees, illustrating differing tolerances to a changing environment. (Abstract ID 12533)

FUKUSHIMA RADIOACTIVITY FOUND IN THE MARINE SNOW AT THE DEEP LAYER IN THE WESTERN NORTH PACIFIC

We carried out the sediment trap experiments in the western North Pacific during autumn, 2010 and summer, 2011. The sinking particles were collected in the area before and after the accident of Fukushima nuclear power plant. Fission-product nuclides Cs-137 and Cs-134 were detected in the sinking particles at 5000 m depth about a month after the accident. The radioisotopes originated from Fukushima were transported to the deep ocean with marine snow immediately. (Abstract ID 9562)

COHERENT MULTIDECADAL ATMOSPHERIC AND OCEANIC VARIABILITY IN THE NORTH ATLANTIC: BLOCKING CORRESPONDS WITH WARM SUBPOLAR OCEAN Winters with frequent atmospheric blocking, in a band of latitudes from Greenland to Western Europe, are found to persist over several decades and correspond to a warm North Atlantic Ocean. This is evident in atmospheric reanalysis data, both modern and for the full 20th century. Blocking is approximately in phase with Atlantic multi-decadal ocean variability (AMV). Wintertime atmospheric blocking involves a highly distorted jetstream, isolating large regions of air from the westerly circulation. It influences the ocean through windstress-curl and associated air/sea heat flux. While blocking is a relatively high-frequency phenomenon, it is strongly modulated over decadal timescales. The blocked regime (weaker ocean gyres, weaker air-sea heat flux, paradoxically increased transport of warm subtropical waters poleward) contributes to the warm phase of AMV. Atmospheric blocking better describes the early 20thC warming and 1996-2010 warm period than does the NAO index. It has roots in the hemispheric circulation and jet stream dynamics. Subpolar Atlantic variability correlates with distant AMOC fields: both these connections may express the global influence of the subpolar North Atlantic ocean on the global climate system. ANNUAL TRENDS IN SEDIMENT FLUX ON THE WAIPOA RIVER MARGIN, NZ

179
The east coast of New Zealand’s north island presents ideal geologic and oceanographic conditions for studying coastal sediment transport in a source-to-sink setting. The region features (-3000 m) mountains, erodible rock, and a vigorous maritime climate, which combine to generate and export ~15 Mt of sediment from the Waipaoa River each year. This study employs three bottom-boundary-layer tripods outfitted with a suite of acoustic and optical sensors designed to evaluate the mechanisms of water and sediment flux along and across the continental shelf for one year. The annual trend for sediment flux is across-shelf with little along-shelf component, driven by small to moderate wave events throughout the year. The notable exception to this rule involved the largest event of our record (July 2010), when the combination of waves (>3.5 m) and discharge (>2000 m³ s⁻¹) resulted in ~40% of the annual across-shelf transport at the near-shelf location, as well as significant along-shelf transport to the north. In this event, the combination of waves and discharge generated a gravity-driven flow, which was influenced by persistent, strong, along-shelf currents. (Abstract ID 11723)

A HIGH-RESOLUTION STUDY OF TIDAL RANGE CHANGES IN THE DELAWARE BAY: PAST CONDITIONS AND FUTURE SCENARIOS

Throughout the Holocene, appreciable changes in coastal and deep-ocean bathymetry are hypothesized to have resulted in large changes in tidal datums. An understanding of these changes is an important contribution to understanding relative sea-level change and to future coastal planning. To test this hypothesis, the Advanced Circulation (ADCIRC) model was used, with paleobathymetry and estimated future bathymetry, in order to model the time-varying tidal behavior of the Delaware Bay. Model runs were conducted on high-resolution grids at various time slices between 15,000 years before present and 1000 years into the future. Open boundary forcing at each time slice was obtained from global model runs. The most significant finding is that tidal ranges have increased by 60-80% in the upper Delaware Bay from 4000 years ago to present day. Additionally, the increase in tidal range shows significant spatial variability.
spatial variability, with the upper bay increasing at a faster rate than the lower bay. The results are consistent with field measurements of relative sea level change over the same time period. (Abstract ID 12217)

SENSITIVITY OF TIDAL BAROTROPIC-TO-BAROCLINIC ENERGY CONVERSION TO DOMAIN SIZE IN A REGION MODEL

M₄ tides in the region around Monterey Submarine Canyon are simulated using a modified version of the Princeton Ocean Model. Barotropic-to-baroclinic energy conversion, (p ′ H′), is diagnosed. Most baroclinic energy entering the canyon originates on S Stope, but there are other, more remote sources within the model domain. Re-running the model with a smaller domain that excludes these remote generation sites decreases baroclinic energy flux in the canyon, but also changes energy conversion throughout the area common to both domains. The remote pressure perturbation (p ′ remote), from internal waves generated outside the common area, enhance or suppresses energy conversion inside the common area depending on its phase relative to the local pressure perturbation (p ′ local). This has three implications: (1) local internal wave generation is modulated by remote generation sites; (2) the internal wave field in regional models may be highly sensitive to domain size; and (3) if p ′ remote > p ′ local and the phase difference is ~180°, negative energy conversion will occur. (Abstract ID 12579)

DEVELOPMENT AND EVALUATION OF AN OCEAN OSSE SYSTEM FOR THE GULF OF MEXICO

A prototype fraternal twin ocean OSSE system has been developed based on two different configurations of the HyBridge Coordinate Ocean Model (HYCOM). Development, evaluation, and calibration of this system is being conducted in the Gulf of Mexico. Goals include designing observing system improvements and enhancements to optimize GoM analyses used to initialize ocean forecasts and provide initial and boundary conditions to nested coastal ocean nowcast/forecast systems, and evaluating the performance of different data assimilation techniques. Errors between the two model configurations used for the nature run and the data assimilation system must have similar magnitudes and properties as the errors between present-day ocean models and the true ocean, and the nature run must also possess a climatology and ocean features that agree with observed properties within pre-specified limits. Analysis of both models demonstrates that these basic criteria are met. Our initial effort will be to determine the impact of targeted ocean observations on ocean analyses used to initialize the ocean component of hurricane forecast models. The goals of this application will be described and initial results will be presented. (Abstract ID 11800)

SURFZONE AND INNER-SHELF TRACER EXCHANGE

During the IB09 field experiment (fall 2009), Rhodamine dye tracer was continuously released near the shoreline at the approximately alongshore- uniform Imperial Beach. A cross-shore array of six frames from the shoreline to 4 m depth measured waves, currents, dye, turbidity, and temperature. Offshore of the surfzone (z ~ 4-6 m depth), vertical and alongshore tracer structure was observed with co-located measurements of dye, turbidity, and temperature using a boat-towed vertical instrument array spanning 1-3 m below the surface and boat-borne CTD casts to the bed. Within the surfzone (~2 m deep at seaward edge), tracer was depth-uniform. Offshore, tracer was patchy in 50-100 m alongshore bands, and dye variability was correlated with turbidity and temperature variability, consistent with ejection by rip current events. The offshore tracer was approximately depth-uniform in the upper 3 m, but very low dye concentrations were observed in limited near-bed measurements in 6 m depth. Weak stratification was observed in the upper 3 m of the water column, while a strong thermocline generally below 3 m may have inhibited vertical tracer mixing seaward of the surfzone. (Abstract ID 10346)

COMMUNICATING OCEAN SCIENCES COLLEGE COURSES: SCIENCE FACULTY AND EDUCATORS WORKING AND LEARNING TOGETHER

As the relationship between science and society evolves, the need for scientists to engage and effectively communicate with the public has become increasingly urgent. Leaders in the scientific community argue that research training programs need to also give future scientists the knowledge and skills to communicate. To address this, Communicating Ocean Sciences (COS) was developed to teach science undergraduate and graduate students how to communicate their scientific knowledge more effectively, and to build the capacity of science faculty to apply education research to their teaching and communicate more effectively with the public. Courses are co-facilitated by a faculty scientist and an educator. Scientists contribute their science knowledge and teaching experience, and educators bring their knowledge of learning theory regarding how students and the public make meaning from, and understand, science. Approximately 25 universities teach COS. The courses incorporate learning theory and provide outreach opportunities for students to apply that theory. Evaluation findings show the courses can be an effective mechanism to introduce scientists to education research and improve post-secondary science instruction, and help future scientists to become more effective communicators. (Abstract ID 9572)

Halvorsen, M. L, Prince William Sound Science Center, Cordova, USA, mhhalverson@pwsac.org
RECENT CIRCULATION STUDIES IN PRINCE WILLIAM SOUND, A FJORD-LIKE SYSTEM IN THE NORTHERN GULF OF ALASKA

Prince William Sound (PWS) is a semi-enclosed embayment in the northern Gulf of Alaska. It receives a substantial amount of freshwater from rain, rivers, and glaciers, and its main basin is significantly deeper than the shelf. Consequently, one might expect its circulation to resemble that of a classical fjord. Observations show this is only partly true. In this talk, recent field studies are presented to explore how several unique features of PWS impact circulation. The first notable difference is that PWS has two significant passages connecting it to the shelf. This means that the subtidal transport in each passage can be largely barotropic, and observations show this occurs in winter. Second, the main sill guarding PWS from deep water exchange is relatively deep and seaward of the largest channel, which allows a vigorous and predictable annual flushing of deep waters when downwelling winds relax. Finally, the interior of PWS is wide compared to both its length and the deformation radius. This creates space for lateral flow, which at times can even develop into a closed-core recirculation. Recent studies have indicated that both small-scale Langmuir turbulence and submesoscale climate variables. (Abstract ID 11427)

Gross Oxygen Primary (GOP) and Net Oxygen Community Production (NOP) were sampled from ocean depths ranging between 60 and 3000 m. Sediment fluxes of MMHg were measured using intact sediment cores and overlying water for use in shipboard benthic flux chambers (SBFCs).

Production of monomethylmercury (MMHg) in sediments on the continental shelf and slope of the northwest Atlantic Ocean during three comprehensive Hg focused oceanographic cruises. We also use scale-decomposed fields to reveal a system far from steady-state. We also use scale-decomposed fields to reveal a system far from steady-state. The effects of Langmuir turbulence, in particular, are examined through comparisons with mixed layer simulations in the absence of Stokes drift. We also use scale-decomposed fields to construct maps of non-dimensional parameters and multiscale couplings. (Abstract ID 11987)

Hammer, R. C., University of Victoria, Victoria, BC, Canada, rhammer@uvic.ca
Circulation and thermal regime in green bay, lake michigan

This project aims to improve our understanding of hypoxia in green bay and the Fox River. Hypoxia has been a problem for decades, and evidence suggests that it may be worsening. Project tasks include: a) development of a hydrodynamic model for Lake Michigan, including Green Bay; b) collection of field data to validate the model and improve predictions of circulation and thermal regime. Initial analysis of modeling results reported by Beletsky and Schwab (2008) revealed low thermocline and thin epilimnion in summer of 2005. Kump and Waples measured severe hypoxia during that period. The model - data agreement suggests that hypoxia in lower Green Bay results from small initial mass of oxygen available for consumption by sediment oxygen demand. The spectrum estimate for Beletsky and Schwab’s (2008) summer temperatures showed a high-energy peak at a period of approximately 8 days. That peak coincides with an oscillation in currents and isotherms measured in summer of 1989 by Gotlib et al. (1990). Field data and model suggest that the cause of oscillation is exchange of water between Green Bay and Lake Michigan. (Abstract ID 12287)

Hamar, R. C., University of Victoria, Victoria, BC, Canada, rhammer@uvic.ca
Circulation and thermal regime in green bay, lake michigan

This project aims to improve our understanding of hypoxia in green bay and the Fox River. Hypoxia has been a problem for decades, and evidence suggests that it may be worsening. Project tasks include: a) development of a hydrodynamic model for Lake Michigan, including Green Bay; b) collection of field data to validate the model and improve predictions of circulation and thermal regime. Initial analysis of modeling results reported by Beletsky and Schwab (2008) revealed low thermocline and thin epilimnion in summer of 2005. Kump and Waples measured severe hypoxia during that period. The model - data agreement suggests that hypoxia in lower Green Bay results from small initial mass of oxygen available for consumption by sediment oxygen demand. The spectrum estimate for Beletsky and Schwab’s (2008) summer temperatures showed a high-energy peak at a period of approximately 8 days. That peak coincides with an oscillation in currents and isotherms measured in summer of 1989 by Gotlib et al. (1990). Field data and model suggest that the cause of oscillation is exchange of water between Green Bay and Lake Michigan. (Abstract ID 12287)

determined within the ETSP mixed layer during El Niño (Jan-Feb 2010) and La Niña conditions (Mar-Apr 2011). Continuous measurements of O2/Ar ratios were made along 105° and 205° between 80°W and 100°W using an Equalized Inlet Mass Spectrometer. Also, O2/Ar ratios and oxygen triple isotope composition were determined on a series of vertical profiles along these transects. Mixed layer O2/Ar ratios, based on O2/Ar ratios converted to C fluxes, ranged from slightly negative to 10 mmol/m2-d. GOP rates calculated from U/234-Th excess indicated 30 to 130 mmol C/m2-d. In both years, higher GOP and NOP rates, as well as NOP/GOP ratios were seen along the northern transect. When the influence of the upwelling on the oxygen mass balances is taken into account, both northern and southern transects indicated significantly higher productivity to the east. Higher GOP and NOP were observed during La Niña conditions in 2011. These estimates of net production will be compared to other approaches, including 234-Th deficiency and floating trap measurements. PROJECT DYNAMO: INVESTIGATING GLOBAL WEATHER AND CLIMATE SYSTEMS IN THE INDIAN OCEAN

This presentation will highlight the participation of NOAA Teacher-at-Sea, Jacquelyn Hans, in a study of ocean-atmosphere interactions in the equatorial Indian Ocean involving meteorologists, oceanographers, and climate scientists from 13 countries in an investigation called Project DYNAMO (Dynamics of the Madden-Julian Oscillation). The Madden-Julian Oscillation (MJO) is a 30-90 day tropical weather cycle that starts over the equatorial Indian Ocean and moves eastward into the western Pacific Ocean where it impacts other global weather and climate patterns such as El Nino-Southern Oscillation (ENSO), Asian monsoons, tropical storm development in the Pacific and Atlantic oceans, and Pineapple Express events. Specialized instruments were deployed and operated on ships, aircraft, and islands in the Southern Indian Ocean, Maldives Islands, Diego Garcia British Indian Ocean Territory, and the Eastern Indian Ocean to collect data and study the MJO at its source. Jacquelyn joined Leg 3 of the research cruise aboard the R/V Roger Revelle in the Eastern Indian Ocean where she worked as part of the profiling operation and deployed a drifter buoy, while teaching her community college class from the ship. THE APPLICATION OF LME CONCEPT FOR ECOSYSTEM-BASED MANAGEMENT IN THE BENGUELA CURRENT LARGE MARINE ECOSYSTEM

The Benguela Current Large Marine Ecosystem is one of the richest aquatic ecosystems on earth; it spans some 30 degrees of latitude, from northern Angola to the eastern shores of South Africa. This ecosystem has high primary productivity (~300 gCm2yr-1) which supports an important global reservoir of biodiversity and biomass of zooplankton, fish, seabirds and marine mammals. In 2007, after over a decade of political negotiations, practical cooperation and research, The Benguela Current Commission (BCC) was formed joining Angola, Namibia and South Africa in a multi-sectoral and inter-governmental approach to ensure sound governance of this aquatic region. The Commission provides a vehicle for the three countries to introduce an ecosystem approach to ocean governance. In recent times, BCC has adopted an LME concept for ecosystem-based management and its five-module approach (productivity, fish and fisheries, pollution and ecosystem health, socioeconomics and governance). This paper describes practical implementation of ecosystem approach in respect of lessons learnt and best practices as well as constraints encountered and measures taken to address them. THE SIGNIFICANCE OF ULTRA-REFRACTED SWELL WAVES TO COASTAL PROCESSES IN SHELTERED AREAS: WITH APPLICATION TO CRISPY FIELD MARSH, SAN FRANCISCO

Deep water surface gravity waves propagating into shallow water may undergo significant changes in their direction due to refraction and other processes. Sometimes the direction of wave propagation can differ from the deep water direction by more than 90 degrees, in which case we refer to the waves as Ultra-Refracted Swell Waves (URSW). URSW can propagate onto sections of coastline that otherwise appear to be sheltered from ocean waves, and in these cases the highly refracted waves can significantly influence coastal processes. For example, Crispy Field Marsh is a small, restored tidal wetland located in the entrance to San Francisco Bay just east of the Golden Gate. The entrance channel to the marsh sometimes closes completely, which effectively blocks the tidal connection to the ocean and disrupts the hydraulics and ecology of the marsh. The most important factor found to bring about the entrance channel closure is the occurrence of large, offshore ocean waves. However, there were also some closure events during times with relatively small offshore waves. Examination of the deep water directional wave spectra during these times indicates the presence of a small secondary peak corresponding to long period swell from the southern hemisphere, indicating that Crispy Field Marsh and San Francisco Bay in general may be more susceptible to long period swell emanating from the south or southwest. A numerical modeling investigation was conducted and confirmed this phenomenon. (Abstract ID 9721)

HURRICANE WAKE RESTRATIFICATION MECHANISMS

As a hurricane passes over the ocean, the intense cycloonic winds draw cold water up from the deep ocean, and make the surface mixed layer much deeper than normal. The result after the hurricane passes is a deep, cold wake which restratifies over time. We analyze the restratification of the cold wakes of Hurricanes Frances, Katrina, and Iggy based on scalings for different processes that can restore the hurricane wake to near the pre-hurricane conditions. The scalings are derived from model results and well-known parameterizations of air-sea heat fluxes, Ekman boundary fluxes, and mixed layer eddies. To obtain realistic scalings, we used satellite observations for temperatures inside the wakes, and climatological data from drifters for temperatures outside the wake and to calculate mixed layer depths. We find that the dominant mechanism for restoration of the surface is the Ekman transport of warmer water adjacent to the cold wake, while sub-mesoscale eddy bolus fluxes have the dominant subsurface effect. The resulting restratification timescales will be compared to approximate restratification times inferred from satellite SST data. (Abstract ID 9987)

"OCEAN DISCOVERY" CRUISES: AT-SEA RESEARCH OPPORTUNITIES FOR THE NEXT GENERATION OF SCIENTISTS.

NOAA’s Cooperative Institute for Ocean Exploration, Research and Technology (CIOERT) explores and studies ocean frontiers with innovation and cutting edge technologies and is committed to bringing “science at sea” experiences to university students. Multidisciplinary “Ocean Discovery” cruises that communicate the excitement of research and discovery to students at a critical stage of their career decision-making have been incorporated into CIOERT’s Florida Shelf Edge Exploration expeditions, including use of the Johnson-Sea-Link submersible (2010) and UConn’s K2 ROV (2011). These high-quality experiences engage students in ocean research via complete research projects from shipboard data collection through presentations. Student research questions are created in association with CIOERT research projects and result in written papers and poster presentations. Students increase their understanding of the scientific process and observe, study, and characterize ocean conditions and benthic and pelagic habitats along the continental shelf. These experiences are transferred to the public, college students, pre-college teachers, and their students via presentations and web-based resources. These “Ocean Discovery” students will likely become tomorrow’s marine scientists, educators, and managers, all working, directly or indirectly, in support of NOAA’s mission. (Abstract ID 12198)

CONSIDERING THE NON-CONSERVATIVE BEHAVIOR OF REFRACTORY DOC IN THE MODERN DEEP OCEAN: OPENING WINDOWS TO ITS DYNAMICS IN ANCIENT OCEANS

Marine refractory dissolved organic carbon (RDOC), holding 660 PgC, has a mean lifetime of thousands of years, with removal considered very slow and steady but incomplete during deep ocean circulation. But unlike RDOC in today’s ocean, this vast reservoir has been suggested as a relatively rigid carbon sink involved in Earth’s past climate changes. Accordingly, RDOC in ancient oceans had to be at times a much larger reservoir than it is today, and that

OBSERVATIONS OF PRESSURE-GRADIENT DOMINATED ALONGSHORE CIRCULATION AT AN EXPOSED OCEAN BEACH

Surfzone dynamics onshore of an ebb-tidal delta and adjacent to a tidal inlet are investigated using measurements collected by an array of pressure sensors and current meters. The instrument array consisted of nine sites, six inside the surfzone extending over 600 m in the alongshore and three wave-current sensors extending over 1.2 km along the ~11 m depth contour outside the surfzone. Alongshore gradients in incident wave height (~10% difference at the 11 m sites), induced by refraction of waves over the ebb-tidal delta, resulted in alongshore wave set-up differences (O(10 cm)) over the 600 m extent of the surfzone instruments. Despite the moderate wave height gradients (O(10°)), alongshore pressure gradients inside the surfzone were often an order of magnitude larger than the radiation stress gradient force, and acting in the opposite direction. As a result, during the week-long deployment, alongshore wave-currents in the surfzone were driven by the pressure gradient. These findings demonstrate that alongshore pressure gradients associated with wave-induced set-up variations can be an important force driving nearshore flows, even in the presence of moderate wave height gradients. IN SITU δ13C OF DISTINCT MARINE PLANKTON POPULATIONS USING FACS AND SWIM-IRMS

Elucidating pathways of carbon flow is critical for understanding carbon cycling and biogeochemistry in the marine environment. Variations in carbon isotopic ratios (δ13C values) of marine particulates can be used to trace sources of organic matter through the ecosystem. While whole-core δ13C differences between specific phytoplankton species have been observed in laboratory cultures under varying nutrient and growth conditions, field measurements have typically been restricted to mixed assemblages differentiated only by size. With fluorescence-activated cell sorting (FACS), specific plankton populations (e.g., diatoms, cyanobacteria) are separated and collected on the basis of either their natural autofluorescence or group-specific fluorescent stains. The δ13C content of sorted cells are then analyzed using a specialized microcombustion interface attached to an isotope-ratio mass spectrometer (SWIM-IRMS). Using this approach we measure an enrichment in diatom δ13C values compared to other measured groups. In situ differences in δ13C among different plankton populations can be exploited to follow carbon flow through successive trophic levels, and throughout organic matter remineralization, sinking, and preservation. PLANKTVOROUS FISH LINK OCEANIC AND CORAL REEF FOODwebs

The food available to planktivorous coral reef fish includes oceanic zooplankton as well as zooplankton groups that originate from and reside within the reef. Using gut content and stable isotope (C, N) analyses, we quantify the relative contribution of reef versus oceanic zooplankton to the diet of nine planktivorous fish species sampled from three distinct reef habitats. Though fish in all habitats consume both oceanic and reef zooplankton, fish diet is habitat-dependent. Oceanic zooplankton comprise 60 to 86% of the diet of fish inhabiting the deep fore reef and 26 to 42% of the diet of fish from nearshore reefs. The dominance of oceanic zooplankton in the guts of forereef fish is paralleled by muscle tissue C isotopes that on average are depleted approximately 2% relative to fish inhabiting nearshore reefs. This study provides direct evidence of significant allochthonous (oceanic) input supporting secondary production in planktivorous reef fish. The role of planktivorous fish as trophic links between oceanic and coral reef food webs is influenced both by reef habitat and by feeding behavior. (Abstract ID 12795)

IMPACTS OF HURRICANE IRENE AT FIRE ISLAND, NEW YORK: A BEACH BUILDING EVENT

The remnants of Hurricane Irene made landfall as a tropical storm on western Long Island, New York on 28 August 2011. Impacts to the barrier beaches of Long Island were expected to be significant, as this area was located within the northeast quadrant of the approaching storm. To assess the impacts of Tropical Storm Irene on Fire Island, a topographic lidar survey was collected after the storm made landfall. In contrast to initial expectations, comparisons of beach volumes with earlier data, in addition to field reconnaissance, indicate that a significant amount of cross-shore transport and infiltration of the beach occurred. Wave conditions from a six day period bracketing Irene were examined and it was found that the wave characteristics during Hurricane Irene were notably different than other severe storms of recent decades. Peak significant wave height values reached nearly 10 m. Long-period waves (17 s) from a southerly direction persisted prior to, during and following the peak of the storm. In contrast, northeaster storms are typically characterized by short period waves prior to the storm peak and long-period waves after the wave height has diminished. These data suggest that the substantial accretion on Fire Island following Irene resulted from the unusually long duration of long period swell throughout the storm, which appears to have resulted in an upward rotation of the shoreface. OBSERVING THE UPPER OCEAN RESPONSE TO GLOBAL TROPICAL CYCLES USING ARGO FLOATS

Tropical cyclones are extreme atmospheric phenomena with implications for the structure and heat transport of the oceans. We use differences between successive Argo float profiles to study changes in mixed layer (ML) depth, temperature, and salinity caused by 705 global tropical cyclones over an 11-year time period (2000-2010 inclusive). In most cases and in all ocean basins, ML temperature decreased and the average ML cooling due to tropical cyclones was about 0.5°C. The ML depth appeared to have an equal probability of deepening or shoaling. We observed larger cooling on the right (left) of tropical cyclone tracks in many cases in the Northern (Southern) hemisphere. This is consistent with the observed locations of cold wake features that have been the subject of many case studies. As part of our analysis, we estimate the fluxes of heat and freshwater due to these storms in the context of global ocean heat and freshwater budgets. (Abstract ID 10651)

A SECOND MOMENT CLOSURE MODEL OF LANGMUIR TURBULENCE

The Reynolds stress equation is modified to include the CL vortex force from the interaction of surface waves and Stokes drift u'w with upper ocean turbulence. An algebraic second moment closure yields an equilibrium model where a component of vertical momentum flux is down the Stokes drift gradient u w in addition to the conventional component down the gradient u w of mean Eulerian velocity. For vertical w' and horizontal u' fluctuations, the momentum flux is (u w)v K u w u w v w, where coefficients K u w and eddy diffusivity K e are distinct. The relevance of this equilibrium model to solutions of the CL equations is demonstrated in comparisons with Large Eddy Simulation (LES) solutions. Rational expressions for the stability functions S u w S u w S w w and S w w are derived for use in second moment closure models where prognostic models for turbulent velocity and length scale include vortex force production terms. The limitation of proximity to the surface, and the model's closure constants, are tuned to LES results. (Abstract ID 11663)

MOLECULAR MARKERS OF NITROGEN AND PHOSPHORUS LIMITATION IN MICROCYSTIS AERUGINOSA

Blooms of the toxic cyanobacteria Microcystis aeruginosa have become common occurrences across the globe and are typically associated with excessive nutrient loading. While phosphorus is the nutrient that most commonly controls primary productivity in freshwater ecosystems, nitrogen limitation of non-diazotrophic cyanobacteria has also been documented. Furthermore, Microcystis blooms often persist even when the inorganic forms of nitrogen and phosphorus are depleted. To better understand the nutritional ecology of Microcystis blooms, we investigated genes that may be regulated by nitrogen and phosphorus limitation. During culture experiments with Microcystis, genes involved in phosphorus assimilation and transport (phoX, psnX, and plbX) were strongly (50- to 400-fold) up-regulated under phosphorus
expression of the gene coding for alkaline phosphatase, limitation and were down-regulated upon phosphorus replenishment. Furthermore, the with alkaline phosphatase activity (\(p<0.05\)).

**COUPLING SEDIMENT TRANSPORT TO BIOGEOCHEMICAL PROCESSES: EFFECTS OF RESUSPENSION ON OXYGEN CONSUMPTION**

Though it enhances the exchange of porewater and solids with the overlying water, the role that sediment resuspension and redeposition play in biogeochemistry of coastal systems is debated. Numerical models of geochemical processes and diagenesis have traditionally parameterized relatively long timescales, and rarely attempted to include resuspension. Likewise, numerical models that represent sediment transport have largely ignored geochemistry. Here, we couple the Community Sediment Transport Modeling System (CSTMIS) to an NPIED (Nitrogen – Phytoplankton – Zooplankton – Detritus) biogeochemical model within the Regional Ocean Modeling System (ROMS). The multi-layered sediment bed model accounts for erosion, deposition, and biodeposition; and has been modified to include dissolved porewater constituents, particulate organic matter, and geochemical reactions. We explore the role that resuspension and redeposition play in biogeochemical cycles within the seabed and in the water column by running idealized, one-dimensional test cases designed to represent a 20-m deep site on the Louisiana Shelf. Results are compared to another model, configured similarly to a standard diagenesis model. Comparing these, the results indicate that resuspension acts to enhance sediment bed oxygen consumption. (Abstract ID 10458)

**THE PRIMARY FACTORS DRIVING ARAGONITE SATURATION STATE IN THE OREGON COASTAL UPWELLING ZONE**

The anthropogenic increase in atmospheric CO2 has led to decreasing ocean pH – also known as ocean acidification. Coastal upwelling zones, like that along the U.S. Oregon Coast, naturally see large variations in pH, CO2, and carbonate mineral saturation states due to the upwelling of high pCO2, low pH source waters. Saturation states are further reduced due to the anthropogenic CO2 burden, which could have ill effects on many types of marine calcifiers. To study what controls the aragonite saturation states (\(\Omega_{arag}\)) in this highly dynamic ecosystem, Submersible Autonomous Moored Instruments for pH (SAMIPh) and for \(pCO2\) (SAMIC\(CO2\)), were deployed in surface waters above the continental shelf and at depth at the shelf break. The pH and \(pCO2\) data were collected for varying durations (from three months to seven months), encompassing spring and autumn transitions and winter on the shelf. The roles of biological productivity, salinity, temperature, and water mass mixing in driving \(\Omega_{arag}\) during each season studied are discussed. Knowing the controls of \(\Omega_{arag}\) in coastal upwelling zones can be used to improve models predicting future \(\Omega_{arag}\) in these regions. (Abstract ID 11307)

**THE TATTERED CURTAIN HYPOTHESIS REVISITED**

Benthic larval settlement dynamics along the US West Coast is often thought to be driven by relaxation of upwelling winds. In this scenario the upwelling front, broken up by squirts and filaments, acts as a “tattered curtain”, retaining coastaly released material and transporting it back to the coast during wind relaxation. Other studies take the approach that settlement is more stochastic and driven by transport in and around coastal eddies. We test these two hypotheses in a coupled ocean particulate tracking model of an idealized eastern boundary current forced by realistic winds. We find that neither of the previous holds for this system on their own, but instead there is a combination of both processes. Settlement patterns are predominantly driven by retention of larvae in an upwelling jet, modulated by coastally trapped waves and interrupted by squirts. This jet is broken up and moved offshore by extended strong upwelling, reducing coastal retention. Spatially discrete, dense packets of coastal material are entrained in the jet and result in locally large pulses of settlement. Lagrangian coherent structures are used to characterize the two transport boundaries associated with jet, one consistent with the upwelling front, and one inshore of this. Findings here are consistent with observed recruitment patterns along the Oregon coast, suggesting the upwelling jet impacts coastal retention in that region. (Abstract ID 11375)

**PREDATOR-PREY INTERACTIONS AND SALINITY TOLERANCE CAN IMPACT HARMFUL ALGAL BLOOM FORMATION IN HETEROSIGMA AKASHIWIO**

Harmful algal blooms (HABs) are ubiquitous and frequent, causing economical and ecological harm in affected areas. We hypothesized that some HAB species experience decreased heterotrophic protist grazing pressure, allowing bloom formation. We investigated the impact of salinity structure and individual movement behaviors on grazing interactions, by concurrently observing population distributions and 3D movement behaviors of the toxic raphidophyte, Heterosigma akashiwo and its heterotrophic protist predators in a 30cm/L tank with a 0-30 psu linear salinity gradient. Heterosigma akashiwo exhibited broad halo-tolerance, rapidly distributing throughout the tank. The predator Oxyrynia marina exhibited a similar broad distribution. In contrast, the predator Pavilla ehrenbergii avoided low salinities. When \(H. akashiwo\) and \(P. ehrenbergii\) co-occurred, 50% of the \(H. akashiwo\) population was inaccessible to \(P. ehrenbergii\). Furthermore, \(H. akashiwo\) exhibited retentive movement behavior (e.g. higher turning rate, slower swimming speed) in areas inaccessible to \(P. ehrenbergii\), resulting in decreased encounter rates, which could ultimately lead to reduced grazing pressure. This coupled physiological/behavioral advantage may be a mechanism that leads to enhanced survival of \(H. akashiwo\) and promotes bloom formation. (Abstract ID 11898)

**A METHODOLOGY FOR PROTEIN EXTRACTION AND PROTEOMIC CHARACTERIZATION IN MARINE MATRICES**

To fully understand the fate of proteins in the environment, improved methods of isolation and analysis within complex environmental matrices are needed. We developed and validated a modified electrophoretic extraction and preparative technique used prior to high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) analysis. Multiple forms of gel electrophoresis were evaluated to enhance recovery of sedimentary protein prior to proteomic characterization and compared with a direct enzymatic digestion of proteins in sediments. Resulting tryptic peptides were analyzed using shotgun proteomics and tandem mass spectra and were evaluated with SEQUEST against multiple databases to determine the ability to confidently identify proteins from environmental samples while minimizing search-time requirements and necessary computational resources. Evaluation of tandem mass spectral data against larger databases with high diversity of proteins did not yield greater numbers or more confidence in protein identifications. Regardless of the protein database used, identified peptides correlated to proteins with the same function across taxa. This suggests that while taxonomic level information remains a challenge, it is possible to confidently identify and assign the function of identified proteins from environmental samples. AN INTERDISCIPLINARY, MULTI-SCALE APPROACH TO MONITORING THE DEVELOPMENT AND SUCCESSION OF HARMFUL ALGAL BLOOM COMMUNITIES IN THE MONTEREY BAY

The abundance of toxigenic diatoms of the genus *Pseudo-nitzschia*, the domocid acid phyco toxin they produce, and associated zooplankton (russes, barnacles, polychaetes, crabs and copepods) were tracked and sampled in Monterey Bay during BloomEx October 2010. Observations from satellites, ships, drifters, autonomous underwater vehicles (AUVs), and environmental sample processor (ESP) robotic molecular detection systems permitted description of ecosystem variability from regional to molecular scales. Different human-in-the-loop and autonomous decision making algorithms developed for the AUVs enabled Lagrangian tracking of phytoplankton bloom patches and targeted water sampling of chlorophyll-a.
fluorescence maxima within the water column. Moor ed ESPs conducted in situ molecular analyses of plankton communities and phyctocyan in near-real-time. Sampling by AUVs, moored ESPs and ships revealed a series of oscillations in the abundance of toxicogenic diatoms and toxin concentrations during the month. These biological oscillations were correlated with changes in oceanographic conditions. Molecular identification of zooplankton identified probable toxin-transfer candidates. Synthesis of the extensive BloomEx data set demonstrates our ability to monitor compositional changes in planktonic communities, examine trophic linkages, and assess how physical processes drive plankton community variability. (Abstract ID 10008)

DIGITAL HOLOGRAPHY OF FEEDING MECHANISMS IN DAPHNIA ON COLONIAL DIATOMS

Size and shape as a limiting factor in grazing among Daphnia is most accentuated in diatoms where single cells are ingested at a higher rate than cells that are part of large colonies. While numerous accounts of ingestion rates are published and the conclusions differ from account to account, little is known about the mechanics of feeding on colonial diatoms by Daphnia and other planktonic grazers. We observed Daphnia swimming freely in a vessel of 125 ml in water with normal densities of colonial diatoms. High-speed digital holography was used to observe encounters between the algae and the grazers. Additional observations using tethered animals revealed the mechanics of capturing and handling of colonial diatoms. The results will be shown in videos. (Abstract ID 9985)

COASTAL UPWELLING AND UPPER OCEAN CIRCULATION IN THE BISMARCK SEA - OBSERVATION AND MODEL SIMULATION

We investigate the upper ocean currents in the Bismarck Sea and related oceanic thermal changes in the western equatorial South Pacific for December 2001 - January 2002; during this period, coastal upwelling occurred along the Papua New Guinea (PNG) coast, and then upwelled relatively cool water spread out over a wider area to the northeast. Simultaneously, strong northeasterly surface winds occurred along the north coast. At that time, a northeastward outflow toward the equator from the PNG coastal area is also found. This northeastward outflow could bring the upwelled relatively cool coastal water, to the western equatorial South Pacific near PNG. The present results indicate that northeastward transport of the cold water is related to the complicated upper-ocean currents in the Bismarck Sea, and that will have strongly affected the upper-ocean thermal change in the western equatorial Pacific near PNG in association of coastal upwelling before the onset of 2002/2003 El Nino event. Similar behavior is also found in CGCM simulation. Furthermore, potential effect of high mountains in the PNG to atmospheric and oceanic variations is examined by regional AGCM. (Abstract ID 10137)

UPWELLING VELOCITIES AND EDDY DIFFUSIVITY FROM THE MEASUREMENTS USED TO COMPARE VERTICAL NUTRIENT FLUXES TO EXPORT POC FLUX IN THE ETSP

The cosmogenically produced radionuclide, Beryllium-7 (half-life = 53.3d), is deposited on the sea surface by rainfall and subsequently homogenized in the mixed layer. The mass balance of its inventory in the water column can be used to estimate upwelling velocities (w) and vertical diffusivity (κ). if the atmospheric input can be established, thus giving insight into vertical transport of nutrients across the upper thermocline. Five the profiles were measured in an area bounded by 10-20S and 80-100W, and used in a one-dimenional diffusion-advection model to determine Kz. Observations indicate an inverse relationship between mixed layer nutrient concentrations and mixed layer 7Be activity, indicating the influence of upwelled nutrient-rich, 7Be-poor water into the mixed layer. Thorium-234/half-life = 24.1d) flux and sediment traps were also used to constrain POC export from the euphotic zone at each site, presumably driven by nutrient fluxes. Values for upwelling velocity, nutrient flux and export POC flux are compared. Neglecting subduction, upwelling velocities were estimated to be up to 0.19m/d, Kz values ranged from 0.90*10^-4-1.55*10^-4m2/s, and diffusive nitrate fluxes across the 1% light horizon ranged from 7.1-4550 umol/m2*d. TOWARD A U.S. ANIMAL TELEMETRY OBSERVING NETWORK FOR OUR OCEANS, COASTS AND GREAT LAKES

The new National Ocean Policy (NOP) calls for strengthening our capacity to observe the nation's oceans, coastal waters and Great Lakes. The U.S. Integrated Ocean Observing System (U.S. IOOS), is providing a framework for the integration of observing capabilities. The development of the ocean observing system began with an effort to integrate physical and chemical data on the oceans, and currently an important near-term goal of IOOS is to increase the amount of biological data in the observing system. One valuable addition to the existing US ocean observing capabilities is animal telemetry observations. In recent years the scale of animal telemetry activities has greatly increased, and there are now a number of self-organized regional networks making concerted efforts to make these data into an operational part of the observing system. A group of scientists including industry, met recently with the goal of establishing a sustainable U.S. Animal Telemetry Observing Network (ATN) and linking observations from this network to U.S. IOOS. The group generated eight recommendations for implementing an ATN and identified potential roles for U.S. IOOS to coordinate the integration of animal telemetry observations. The group consensus was that an observing system that monitors animals on a range of temporal and spatial scales will yield both short and long-term benefits, fill knowledge gaps and advance many of the NOP Priority Objectives, particularly EBM and CMSF. IMPACT OF VARIOUS IRON SOURCES TO TASMAN SEA PHYTOPLANKTON: FROM BIOAVAILABILITY TO COMMUNITY SHIFT

The effect of different iron forms was studied at two sites in the Tasman Sea to mimick allochthonous (terrestrial (fulvic acid) and atmospheric (two Australian desert dusts)), and autochthonous sources (monosaccharide, exopolysaccharide, and siderophore). In these experiments, the total added iron was kept constant (2nM) and compared with inorganic iron or absence of iron enrichment. The bioavailability of these different forms of iron was measured on size fractionated phytoplankton and their impact on phytoplankton was measured following 4 day incubation. The phytoplankton community structure, photosynthetic health, primary productivity, nutrients, iron chemistry; and humic-like substances were measured. Results demonstrate that iron sources have different bioavailabilities to different phytoplankton size fractions and exopolysaccharide was the most efficient to enhance iron bioavailability. Following incubation, iron bound to fulvic acid and siderophore elicited little response, however exopolysaccharides and dust induced increased phytoplankton biomass and a community shift. Different responses were measured between different iron forms and sites, indicating that both iron source and the original community are important factors to consider for the prediction of...
the impact of iron input to the phytoplankton community. (Abstract ID 10892)

PLUGGING THE HOLES: EVALUATIONS AND DESIGNS FOR ACOUSTIC ARRAY INTEGRITY IN A COMPLEX COASTAL ECOSYSTEM

Ecological hypotheses concerning the movement of marine animals are sensitive to Type-II errors: the failure to detect the passage of an individual into or out of an ecosystem. The hypothesis that Atlantic Salmon are able to close their life cycle within the Bras d’Or estuary of Cape Breton, Canada can be tested by acoustically tagging smolts and tracking their return to natal rivers without migration into the NW Atlantic. This is easier said than done, despite the fact that there are only three possible avenues of transit from this complex, 1200km2 estuary. These channels include a broad range of bathymetric, hydrodynamic, and hydrological features that severely compromise the ability of acoustic receptors to detect tags. We have conducted a series of detailed tests that demonstrate high probability of type-II error (low power) as a result of acoustic shadowing, turbulent and turbidity scattering, and pycnocline reflection. We conclude that tagged fish will often be able to transit without detection even in shallow, narrow channels much smaller in cross-sectional area than the optimum range of receivers. We suspect that this is a common problem with acoustic tracking arrays in coastal and inland aquatic ecosystems, and identify tactics to evaluate and design such arrays for greater statistical power. IRON FLUXES FROM THE SHELF REGIONS IN THE SOUTHERN DRAKE PASSAGE DURING THE AUSTRAL-WINTER 2006

Spatial distributions of dissolved iron (Fe), manganese (Mn) and aluminium (Al) in the upper 500m in the region near Antarctic Peninsula (AP) during the 2006 austral-winter are consistent with diagnostically-produced sedimentary sources and also with data obtained in the region during the 2004 austral-summer. Nearest King George Island (KGI) elevated levels of dissolved Al, Fe and Mn are found uniformly down to the sediment water interface in high energy regions above the shelf. These distributions contrast with the offshore Antarctic Circumpolar Current (ACC) where very low concentrations of Fe coincide with high nutrients and low concentrations of chlorophyll (HNLC). In the Bransfield Strait (BS), the elevated trace metal concentrations correspond to the flow path of the Bransfield current near KGI. This enriched plume can also be seen exiting the BS, between Clarence and Elephant islands into the Scotia Sea where it mixes with the high nutrient ACC waters leading to high productivity in this region during the growing season. CAN DOC INFLUENCE THE AVAILABILITY OF THE CLIMATE FEEDBACK GAS DMS?

Dimethylsulphide (DMS) production in the ocean represents ca. 40 % of the global input of volatile sulphur to the atmosphere, where it can affect cloud albedo and may have a role in global climate regulation. Remarkably ca. 90 % of all the DMS produced in the ocean never escapes to the atmosphere, but up to now we had not fully understand where it went to. Our research along with a growing body of evidence strongly suggests that most of the DMS removed is actually oxidised to DMSO. Furthermore, it suggests this pathway is ubiquitous in the oceans and may represent an important mechanism by which marine bacteria provision their cellular energy requirements. More importantly, it is now becoming apparent that the amount and rate of DMS oxidation may be influenced by the availability of dissolved organic carbon (DOC), meaning that the availability of DOC may have important implications for the cycling of DMS and climate feedback, and in turn the availability of DMS may influence the rates of biogeochemical cycling and energy derived from the DOC pool by marine bacteria. SINGLE-NUCLEOTIDE POLYMORPHISMS (SNPS) SHED LIGHT ON TRANSPORT-RELATED CONDITION AND CONNECTIVITY IN CORAL REEF FISH LARVAE

While there is potential for long distance larval dispersal, recent research indicates that local retention of larvae may be more important in replenishing coral reef fish populations than influx from distant sources. Because of carryover effects, larvae with different levels of condition in the plankton may differ in their post-settlement mortality. Thus, in order to better understand the relative contributions of local retention and long-distance dispersal in maintaining reef fish populations, it is necessary to examine the relationship between larval condition and dispersal pathways. We have used high-throughput sequencing to identify over 56,000 SNPs from 385 bluehead wrasse. By using a subset of these SNPs to genotype bluehead wrasse larvae collected from locations along and upstream of the Florida Keys reef tract, we can identify particular loci that covary with condition-related traits (growth rates, RNA/ DNA ratios), and document sparse differences in spatial distributions of particular SNPs, especially among nearshore and offshore water masses. Additionally, we can investigate differences in the frequencies of particular SNPs among newly hatched larvae, and older (longer-surviving) larvae and juveniles as a means of identifying loci under selection. MAPPING SPATIOTEMPORAL PATTERNS IN TIGER SHARK HABITATS USING SATELLITE TECHNOLOGY

Twenty-two tiger sharks (Galeocerdo cuvier) were tagged with SPOT tags near Bermuda between 2009-2011. Shark tracks were filtered for quality and swimming behavior. We matched GPS locations of the sharks with ocean surface data (SST, Chla, ocean color, biomass) measured by NASA’s MODIS Aqua satellite, as well as bathymetry and distance to land measurements. Local regression and distance based modeling techniques were applied to identify and predict ideal shark habitat type based on satellite data. Most tiger sharks followed similar migration patterns. We found a strong interaction between shark location and solar properties as well as sea surface temperature. We used these sharks to develop a dynamic habitat model that spatially and temporally predicts the location of tiger shark habitat. This is the first study to integrate tiger shark tracking efforts with the dynamic ocean properties that can be measured remotely by satellites. These habitat maps can be integrated into ecosystem and climate models to test the interaction between apex predators and global change. (Abstract ID 10236)

CONCORDANT PHYLOGEOGRAPHIC PATTERNS ASSOCIATED WITH THE MAJOR HEADLAND OF CAPE MENDOCINO IN NORTHERN CALIFORNIA

Coastal geographic features are important determinants of dispersal for marine larvae. We consider the role that Cape Mendocino may play in limiting larval dispersal along the coast of northern California. Though Cape Mendocino is a prominent headland, it has been largely ignored in the eastern Pacific phylogeographic literature. We review and synthesize phylogeographic studies that include sampling sites north and south of Cape Mendocino and discuss oceanography and topography of the cape as potential mechanistic drivers of larval dispersal. Slightly more than half of species showed significant genetic structure around this headland. This result suggests, for some species, Cape Mendocino may provide a barrier to larval dispersal. This concordant phylogeographic break is coincident with a large persistent upwelling jet, an offshore cyclonic eddy, poleward-moving water in the south, and a large stretch of sandy habitat to the north, which may combine to reduce larval dispersal across the cape. If populations north of Cape Mendocino have higher connectivity with populations in Oregon than with those in central California, marine spatial planning must occur at a multi-state scale to reach conservation goals. (Abstract ID 12170)

The West Coast Governing Agreement (WCGA) was formed by the governors of California, Oregon, and Washington and spans the California Current Large Marine Ecosystem (CCLME). In 2006, the governors developed a high-level policy directive and formalized an action plan to address West Coast’s most pressing ocean issues. Ten Action Coordination Teams (ACTs) were established to take on-the-ground steps in ocean and coastal policy at local, state, and regional levels by bringing together science and policy experts. As a Regional Ocean Partnership, the WCGA interacts with the National Ocean Council and can assist in implementing national ocean policy priorities, which largely mirror regional priorities. The West Coast Sea Grant programs jointly funded four Fellows to assist the WCGA to coordinate across ACTs, promote research and information priorities for the West Coast, and facilitate the formation of a West Coast regional data network to increase access to geospatial data. These efforts will help the WCGA assimilate scientific data and information into ocean resource policies and practices within the CCLME, implement their plan, and maintain a leadership role within the National Ocean Policy. Transition Decades for Ocean Acidification in the California Current System  
Due to seasonal upwelling the California Current System (CCS) has a naturally low pH and aragonite saturation state (Ωarag), making it particularly prone to ocean acidification. We define transition decades as the time period when chemical changes induced by the long-term trends exceed those experienced over the annual cycle. To do so we use a CCS set up of the Regional Ocean Modeling System (ROMS). Despite the large variability of pH and Ωarag, the present day levels are already distinctly different from those during the preindustrial era. By 2040 pH and Ωarag of the nearshore 50 km are expected to be distinctly different than today. The aragonite saturation horizon is projected to permanently shoal into the upper 75 m in approximately 2030. The model tends to underestimate the annual variability of the system and overestimate pH and Ωarag, which implies that transition decades are expected later, while permanent undersaturation is expected earlier. We show that organisms of the CCS will be forced to rapidly adjust to conditions that are inherently chemically challenging and also distinctly different from the present day. (Abstract ID 11119)

Spray Effects on High-Wind Speed Momentum Fluxes in Both Marine and Fresh Water  
Understanding the coupling between the atmosphere and ocean in extremely high winds is of significant interest due to its effect on hurricane intensities. One of the most challenging aspects of this problem has been isolating the sea spray contributions to the momentum flux. Although freshwater laboratory observations offer highly repeatable drag coefficient measurements for wind speeds up to 50 m/s, the question exists of whether they appropriately represent marine sea–spray effects. To evaluate the differences between seawater and freshwater spray on air-sea momentum transfers a series of laboratory experiments has been conducted in the Air-Sea Interaction Salt-water Tank (ASIST) of the University of Miami. Droplet size distributions were measured in both seawater and freshwater using a Cloud Droplet Imaging Probe (CDIP) over a range of wind speeds up to U10N of 50 m/s. Bulk momentum exchange coefficients (CD10) were directly observed using a momentum budget technique. A key aspect of this approach is that the total stress was observed (both interfacial and spray induced). Although corrections are required to account for the local spray generation and for spray droplets that evaporate out of the system and not returned to the surface, with the existing data we can evaluate the differences between the marine and freshwater spray effects. (Abstract ID 10375)

Factors Contributing to the Atmospheric Decadal Warming of Sub-Polar North Atlantic 2001 - 2011  
Recent ocean observations demonstrate a strong warming trend in the sub-polar North Atlantic over the past two decades. This is concurrent with typically milder than usual winters over the North Atlantic region. Atmospheric warming can be considered as a major factor that contributes to the weakening of winter cooling at the surface and intermediate layers of the ocean. We examine links between the recent warming of the sub-polar North Atlantic and fluctuations in patterns of occurrence of large scale North Atlantic atmospheric regimes. These regimes are defined by performing cluster analysis on reanalysis derived 500 mb geopotential heights, to allow identification of more subtle distinctions than possible with more standard indices. The clusters are fit using fuzzy membership functions so as to determine a consistent measure of the atmospheric state. These memberships are well correlated with Labrador Sea Ocean temperature. We discuss the influence of variation in atmospheric synoptic scale features relating to these regimes on the ocean temperature. (Abstract ID 12892)

Comparison of Altimetric DataSets Near the US West Coast  
Correction algorithms and orbits for satellite altimeter missions have been successfully improved over time; however, these improvements were focused on the deep ocean while coastal measurements remained undeveloped due to land contamination and measurement errors associated with the different oceanic physics in shallow and coastal waters versus deep water. To alleviate the lack of accurate coastal data, several datasets have been designed for coastal regions by using tailored correction algorithms or integrating tide gauge data with the altimetric data. But, how accurate are these datasets? In this study we used the tide gauge augmented coastal altimetry dataset developed by Oregon State University/Cooperative Institute for Oceanographic Satellite Studies (OSU/CIOUS) as “truth” to evaluate several along track altimetry data sets within 0.75 degrees of the US West Coast. Three along track altimeter datasets: French coastal altimetry dataset (PISTACH), multi-mission integrated altimeter data from NASA, and OST/Mason-GDRs with enhanced radiometer correction are compared to the OSU dataset in this region to evaluate the differences in the various coastal datasets and to perform an initial assessment of their accuracy. (Abstract ID 12591)

Hawley, N., Great Lakes Environmental Research Laboratory, Ann Arbor, USA, nathan.hawley@noaa.gov

Observations of Sediment Transport During the Winter in the Laurentian Great Lakes  
The Laurentian Great Lakes are subject to ice cover, particularly in the shallower areas, for several months each winter. Since most sediment resuspension in the lakes is caused by surface wave action, the presence of significant ice cover can inhibit sediment movement during these periods. Direct observations of sediment resuspension and transport during the winter are difficult to make, but time series observations of water transparency, temperature, current velocity and wave action were made at several sites in Lake Erie during the winters of 2004-2005 and 2010-2011. The observations show that the presence of ice over significant portions of the lake essentially eliminated wave action, so little or no resuspension occurred, and the water column became cleared of suspended material. Since ice is an annual feature of the lake’s climate, its presence causes a yearly episode of sediment sequestration on the bottom prior to resuspension and transport after the ice breaks up. (Abstract ID 10395)

AIR-SEA INTERACTIONS ON TITAN: WIND DRIVEN CAPILLARY-GRAVITY WAVES; HARD TO DETECT OR NON-EXISTENT?
Saturn's moon Titan has lakes and seas of liquid hydrocarbons in a dense atmosphere, an environment notionally conducive to generating wind-waves. However, Cassini spacecraft observations so far show no indication of wave activity. Here we review common models for wind-wave generation and apply them to the Titan environment. Results suggest U10 thresholds of 0.3-0.7 m/s for likely lake compositions, depending on liquid viscosity. This reduced threshold, compared to Earth, results from Titan's increased atmosphere-to-liquid density ratio and reduced gravity and surface tension. While available observations have been acquired near Equinox, when predicted wind-speeds are below this threshold, future observations will be acquired during Northern Spring/Summer, when wind-speeds above the threshold are predicted. Once gravity-capillary waves begin to grow, gravity waves will soon follow, leading to a fully developed sea. For a given wind-speed, Titan's reduced gravity will lead to H, 1/3) ~ 2 times greater than Earth. Cassini's ongoing observations may detect such seas. However, the low winds speeds predicted on Titan suggest that H), 1/3) will remain below ~0.6 m, which is below the maximum potential tidal amplitude of the largest seas. (Abstract ID 10721)

PA AND TH DISTRIBUTIONS ALONG THE GEOTRACES NORTH ATLANTIC TRANSCET
The oceanic distribution of $^{218}$Pa and $^{230}$Th is the combined result of production via uranium decay, adsorption-desorption reactions with particulate matter, and redistribution by ocean circulation. Motivated to deconvolute these influences for their use as proxies, we present initial results for dissolved $^{218}$Pa and $^{230}$Th concentrations in the contrasting oceanographic settings sampled during the 2010 leg of the U.S. GEOTRACES North Atlantic Transect. Small but detectable isopycnal gradients in the concentration of dissolved $^{230}$Th exist across a zonal transect between Mauritania and Cape Verde. Boundary scavenging, in response to high biological productivity and particle flux off the Mauritian margin, may be less dramatic than once thought but potentially quantifiable here. Dissolved $^{218}$Pa concentrations and dissolved $^{218}$Pa/$^{230}$Th ratios at mid-depth (1000-2500 m) in the Cape Verde transect are much larger than in the more northerly stations (30-40°N, 10-20°W). We speculate this gradient reflects some combination of water mass ageing and the much greater fluxes of biogenic opal in the Mauritian upwelling region. Finally, vertical concentration gradients in $^{218}$Pa near the seafloor suggest enhanced removal of this isotope at the seabed. (Abstract ID 10514)

RESPONSE OF BENTHIC FORAMINIFERA TO A NATURALLY CO2-RICH COASTAL HABITAT IN FLENSBURG FJORD (SW BALTIC SEA)
It is expected that the calcification of unicellular foraminifera is negatively affected by the ongoing acidification of the oceans. Nevertheless, compared to the open ocean, already today these organisms are subjected to much more adverse carbonate system conditions in coastal and estuarine environments such as the Baltic Sea. Although foraminifera are abundant in the brackish Hensburg Fjord, test dissolution of living benthic foraminiferal assemblages was observed during the seasonal cycle. Similar levels of test dissolution were observed, when living Ammonia aequirotia were exposed to elevated pCO2 levels from 929 to 3130 µatm in a culturing experiment. These data indicated drastic effects of the prevailing acidotic conditions on benthic foraminifera. In this study, we compared the seasonal changes of the carbonate chemistry (pCO2, pH) and the response of the foraminiferal community in more detail on bi-monthly cruises to Hensburg Fjord. We observed large seasonal fluctuation of bottom water pCO2, and permanent low pH. Further, foraminiferal assemblages were characterized by seasonal community shifts. Despite adverse pCO2, and pH conditions, most tests were intact which indicates the ability of foraminifera to cope with fluctuating pCO2. These results emphasize the need to understand the biological control of the calcification process in foraminifera. (Abstract ID 12300)

PARAMETRIZATION OF SUBMESOSCALE PARTICLE TRANSPORT IN THE GULF STREAM REGION USING LAGRANGIAN SUBGRIDSCALE MODELS
We study the Lagrangian transport in the Gulf Stream region, which exhibits clear indications of strong submesoscale activity from both models and observations. A hybrid approach is put forward, in which the modeled transport is based on the deterministic Lagrangian Coherent Structures (DGLS) over the mesoscale range and the statistical Lagrangian subgridscale (LSGS) models over the submesoscale range. Two HYCOM solutions at different resolutions, namely with 1/12 and 1/48 degree horizontal meshes respectively, are considered, and a measure of relative dispersion, the scale-dependent finite scale Laxpovun exponent, is used as our main metric to diagnose their differences in terms of transport. The particular focus of this study is on correcting the underestimation of submesoscale dispersion regime in the 1/12 degree solution, while the 1/48 degree resolution case and an existing observational data set indicate a trend toward much higher dispersion. Three LSGS models that had been developed on the basis of statistical considerations are investigated in order to tackle the multi-scale ocean transport problem. We characterize them and define their parameter ranges that yield an improvement in multi-scale relative dispersion. (Abstract ID 9760)

PACIFIC TOP PREDATOR HABITAT SHIFTS IN A CHANGING CLIMATE
Climate change scenarios have predicted an average rise from 1.4°C to 2°C which could effect the habitat and distribution of many marine species. We used spatially explicit habitat models (e.g. generalized additive mixed models) to examine present-day distributions and foraging habitat of 23 top predator species in the Pacific from 2001-2009 as a function of fixed bathymetric variables, sea surface temperature, wind, Ekman pumping, mixed-layer depth, and chlorophyll-a. Consequently we used a 1° and monthly resolution climate models from the Geophysical Fluid Dynamics Laboratory to predict potential habitat under future scenarios. We found oceanographic changes, such as the northward migration of the transition zone that
affected top predator biodiversity throughout the Pacific and highlighted potential changes in important conservation corridors. (Abstract ID 9917)

ECOGENOMICS OF THE DEEPWATER HORIZON SPILL

The explosion on April 20, 2010 at the BP-leased Deepwater Horizon drilling rig in the Gulf of Mexico off the coast of Louisiana, resulted in oil and gas rising to the surface and the oil coming ashore in many parts of the Gulf. It also resulted in an immense oil plume 400-500 ft deep. Despite spanning more than 600 feet in the water column and extending more than 10 miles from the wellhead, the dispersed oil plume was gone within weeks after the wellhead was capped — degraded and diluted to undetectable levels. Ecoinformatics enabled discovery of new and undersampled species of oil-eating bacteria that apparently lives in the deep Gulf where oil seeps are common. Using 16s rRNA sequences, functional gene arrays, done libraries, lipid analysis, phenotypic microarrays, metagenomes, metatranscriptomes, single cell sequencing, stable isotope analysis in combination with a variety of hydrocarbon and microntinutrient analyses we were able to characterize the deep-sea microbial ecosystem and the effect of the oil spill. EFFECT OF THE GULF STREAM ON WINTER EXTRATROPICAL CYCLONE OUTBREAKS

A high-resolution, regional coupled atmosphere-ocean model is used to investigate strong air-sea interactions during a rapidly developing extratropical cyclone (ETC) off the east coast of the United States on 22-23 January 2008. In this two-way coupled model, wind stress and net heat flux from the Weather Research and Forecasting (WRF) atmosphere model and sea surface temperature (SST) from the Regional Ocean Modeling System (ROMS) are exchanged via the Model Coupling Toolkit (MCT). Model validations against in-situ buoy and ocean glider data show that the coupled-air-sea model accurately reproduces the strong storm winds, fluctuations in sea level pressure, persistent ocean cooling, and upper ocean temperature structures observed. It is found that the air-sea interactions near the Gulf Stream are important for generating and sustaining the ETC. In particular, locally enhanced winds over sharp SST discontinuities induce large surface heat flux which cools the upper ocean by up to 2°C. Detailed model analyses show the ocean-to-atmosphere heat flux dominates the upper ocean heat content variations, and that the synoptic surface wind convergence (SWC) is proportional to the Laplacian of sea level pressure and sea surface temperature. SWC induces strong upward vertical motions throughout the marine atmospheric boundary layer and enhances ocean heat loss, supporting rapid ETC intensification. (Abstract ID 12814)

WHAT IS HAPPENING AT THE NORTHWEST CORNER OF THE NORTH ATLANTIC CURRENT?

The North Atlantic Current (NAC) travels northward east of the Grand Banks until approximately 50°N where it makes a sharp turn to the east. Previous analysis of sea level variability in this region, known as the Northwest Corner, showed a quasi-regular production of anticyclonic eddies, some of which appear to disappear in place. It was hypothesized that these eddies become denser due to a large latent heat flux to the atmosphere and that they sink in place. To address these ideas, four high resolution and two broader scale hydrographic surveys in two separate expeditions spanning a three-month period during Spring 2011 were undertaken. Results from these surveys as well as output from the data assimilative HYCOM model of this region will be discussed. Evidence of interaction of eddies with the NAC, including the spin up and decay of eddies, and interleaving and subduction between the different water masses in the region will be presented. THE SOUTHERN OCEAN AND ITS CLIMATE IN CCSM4

The Southern Ocean is a key area in the climate system for many reasons, and good representation of its mean state, internal variability, and response to external forcing is essential for the fidelity of coupled climate simulations. Here we present results of our evaluation of the Southern Ocean in the Community Climate System Model v4 (CCSM4). The CCSM4 is a state-of-the-art coupled climate model, and a suite of simulations have been performed following the protocol of the Coupled Model Intercomparison Project, phase 5 (CMIP5). We focus on the representation of the major water masses of the Southern Ocean (Antarctic Bottom Water, Subantarctic Mode Water, and Antarctic Intermediate Water), compare water mass properties and tracer distributions to observations, and address the representation of the Antarctic Circumpolar Current and the interocean exchanges that take place along the northern edge of the Southern Ocean. EFFECT OF THE WIND STRESS ON THE VARIABILITY OF THE YELLOW SEA BOTTOM COLD WATER IN SUMMER

Sea surface temperature is important to primary products and marine life. The Yellow Sea Bottom Cold Water (YSBCW) colder than 10°C is observed below the thermocline in summer. The cold water persists in spite of surface heating for the whole year. Many scientists have interested in this unique water mass. This study investigates interannual variability of the YSBCW and their causing mechanisms. The observed temperature by the National Fisheries Research & Development Institute in the southern Yellow Sea shows that remarkable two modes of the southern boundary location of the YSBCW. Interannual variation of the YSBCW has strong relation with the southerly wind stress in summer whereas they have weak relation to the previous winter temperature. This implies that southerly wind may play important role in driving southward flow of the YSBCW. Detail dynamics will be explained with numerical model experiment. (Abstract ID 11121)

HISTORICAL PRIMARY PRODUCTION IN THE EASTERN GULF OF MEXICO

Examination of short and long-term impacts of the Deepwater Horizon spill and the resulting dispersal of crude oil, oil-dispersant mixture and the weathering products on primary production in the eastern Gulf of Mexico is complicated by a lack of systematic and long-term primary production measurements. We have compiled and synthesized primary production data from 1992 to 2010 for this region from a variety of sources. Values in offshore oligotrophic areas were generally low, <1.0 C g m(-2) d(-1), except in localized areas with blooms of Ncutinizing cyanophyte Trichodesmium or in one instance, a subsurface bloom of Phaeocystis spp. where values ranged up to 4.23 C g m(-2) d(-1). Size fractionated data generally showed a trend of equivalent production occurring in the 0.2–3.0 µm and >3.0 µm fractions in these regions. Production in coastal regions was elevated, up to 5 C g m(-2) d(-1) with values exceeding 15 C g m(-2) d(-1) in areas of Karenia brevis blooms. This variability suggests that documenting and predicting impacts of the spill on primary production will be both complicated and challenging. (Abstract ID 11468)

EXAMINATION OF KEY PROCESSES INVOLVED IN THE BIOCHEMICAL CYCLING OF MANAGANESE IN THE OCEAN

Mn is biologically important for phytoplankton as it is critical for many redox enzymes required for photosynthesis, in particular in Photosystem II where it converts water to oxygen. Many marine organisms also utilize Mn as the metal centre in superoxide dismutase (SOD). SODs are essential for intracellular defences against reactive oxygen species (ROS) like superoxide. In oxygenated seawater soluble Mn(II) is slowly oxidized (biotic or chemically) to insoluble MnO2, which precipitates out of the water column. In the sulfidic ocean, ROS can reduce MnO2 back to Mn(II) introducing a redox cycle. Recent work suggests that Mn(III), which is a transient intermediate between Mn(II) and MnO2, may play an important role in both, the Mn and Fe biogeochemical cycles, however until now it is unidentified how and if this species is stabilised in the ocean. Here we will present data for Mn concentrations, speciation and its kinetic reactivity with ROS from two research cruises (M83-1 and M83-17) in the Tropical Atlantic. In this presentation we examine the current evidence for Mn(III) in the euphotic zone of the open ocean. (Abstract ID 11078)

CHARACTERIZATION OF THE MAIN FRACTION OF DISSOLVED ORGANIC MATTER FROM DIVERSE OCEANIC ENVIRONMENTS BY REVERSE OSMOSIS COUPLED WITH ELECTRODIALYSIS

Only a small fraction of marine DOM is readily identifiable. Determining the chemical nature of the remaining fraction of oceanic DOM has been impeded by lack of efficient and non-fractionating methods for isolation and desalting. Here, reverse osmosis-electrodialysis (RO/ED) was used for isolating a representative DOM fraction (~75%) for analysis by solid-state 13C-NMR. Samples were obtained from biogeochemically diverse environments; i.e., photobleached surface gyre, productive coastal upwelled, oxygen minimum, deep Atlantic, and old deep Pacific waters. Advanced NMR spectral editing revealed new insights into carbohydrate biodegradation, and preservation of carboxyl groups and condensed aromatic structures (deep sea samples). Quaternary alginic carbon were identified as an important component of bio-refractory carbohydrates. However, despite some differences, these diverse samples yielded remarkably similar DOM compositions. Our results support the 3-pool DOM model (labile, semi-labile, and refractory). Evidence of ‘background’ refractory carbon was seen throughout the ocean DOM samples, and the high carboxyl signal in the deep Pacific sample supports the hypothesis that a major fraction of the refractory pool is carboxyl-rich alicyclic material (CRAM). (Abstract ID 11250)

QUANTITATIVE ASSESSMENT OF MACROINVERTEBRATE COMMUNITIES IN AN URBAN NEW ENGLAND WATERSHED

The Neponset River watershed is 1 of 5 urban watersheds flowing into Boston Harbor. The top 5 land-uses in the watershed are forest, golf-course, residential, industrial, and wetland. Physical and chemical analyses showed that land use impacts water quality in the watershed. The goal of this study was to assess water quality using aquatic macroinvertebrate bioassessments and relate bioassessment scores to land-use type in the watershed. In summer of 2010, we deployed a cluster of 3 Hester Dendy artificial substrates at 8 total sites; 2 reaches for each for golf, residential, industrial, and forested land-use treatments. Community parameters examined included EPT/Chironomids ratio, total number of taxa collected per site, Shannon-Wiener Diversity Index, and Invertebrate Community Index. We expect forested areas to have higher water quality than the more perturbated land-uses as shown in habitat assessments and physical and chemical water analyses. Our results can be used to show the utility of assessing water quality via bioassessment, comparing water quality of different land uses, and be used to make management decisions to improve water quality in the watershed. (Abstract ID 10577)

WAVE-GENERATED, WIND-MIXED NEAR-SURFACE SHEAR OBSERVED OVER A TIDAL FLAT

Around high tide over a flooded tidal flat, vertical shear measured 0.13-0.4 m beneath the sea
surface by upward-looking Acoustic Doppler Profilers (ADPs) was usually aligned with the wind. However, shear did not increase with increasing windspeed, likely owing to an increase in wave heights and wave-generated mixing with increasing wind. The associated increase in water-side drag coefficient with windspeed was predicted, with substantial scatter, by a model for near-surface mixing by breaking waves. A depth-independent eddy viscosity model yielded only slightly less skill than a fitted depth-dependent model. Farther (0.3-0.6 m) from the surface the model skill was low. Wave heights tended to increase with increasing water depth. Consequently, the simulated wave-generated surface eddy viscosity tended to increase with increasing depth. (Abstract ID 12839)

OCEAN PLUME AND TRACER MODELING FOR THE FUKUSHIMA DAI-ICHI EVENT
NCEP/NWS deployed particle tracing to predict the movement of radionuclides in the ocean shortly after the Japanese Nuclear disaster near Fukushima. Daily nowcast/forecast fields from 1/12 HYCOM (RTOS-Global) model output were used to track inert particles at the ocean surface, assuming that the surface behavior is reasonably representative for the ocean mixed layer, and that the radionuclides will mostly be contained in and distributed by the upper mixed layer of the ocean. With the particle tracing information, NCEP produced estimates of retention times of radionuclides near the coast, as well as dispersion time scale of these materials through the Pacific Ocean, particularly by persistent current systems like the Kuroshio and the extension, and the Oyashi. This helped identify both potential safe areas in the Pacific, and areas of potential exposure on the time scales of weeks to months. Full tracer computations capability of HYCOM has also been used to predict the dispersion of radionuclides in a nested North West Pacific subregion model within RTOS-GLOBAL. The initializations and boundary conditions of the nested subregion were incrementally updated daily from the nowcast fields of the global model. Some preliminary results from the tracer computations will also be presented. (Abstract ID 11761)

HIGH RESOLUTION RECONSTRUCTION OF PALEOENVIRONMENTAL VARIABILITY DURING THE LAST 20 KYR IN THE SOUTH EAST LEVANTINE BASIN, EASTERN MEDITERRANEAN
The eastern Mediterranean Sea is particularly sensitive to climate change. Its sediments record not only global climate periodicities such as glacial/interglacial periods and shorter time-scale climate oscillations, but they do so in an amplified manner (e.g. sapropels). Sediment deposition in the southeastern Levantine Basin are perfect recorders for high-resolution studies, since the Nile maintained a continuous high sedimentation rate. Here we present a well-dated (210-Pb and 14-C), comprising a detailed continuous record (~5-25 yr per sample) of the last 20 ky. Results of the bulk sediment inorganic geochemistry, grain size, foraminiferal C/O isotopes, organic C/N isotopes, and TOC are used to investigate short time scale paleoceanographic variability. We will focus on productivity, fresh water (Nile) and deep water oxygenation changes from the Last Glacial Maximum through the Holocene with emphasize on times of global abrupt climate change (H1, B-A, Y .Dryas, African Humid Period, and 8.2 kyr event). (Abstract ID 11064)

ACCLIMATION OF THE COLD WATER CORAL, LOPHELIA PERTUSA TO PREDICTED RISES IN ATMOSPHERIC CO2 AND SEA TEMPERATURES
Cold-water corals are amongst the most three-dimensionally complex deep-sea habitats known and are associated with high local biodiversity. Despite their importance, little is known about how these organisms will face the face of predicted future climate change. Currently, the long-term synergistic effects of projected increases in atmospheric pCO2 and sea temperatures upon the cold-water coral Lophelia pertusa are unknown, and studies to date have only examined L. pertusa response to either increased temperature or increased pCO2 on short time scales. Here, we present data on the effects of increased sea temperatures (by 3°C) and increased pCO2 (750 and 1000ppm) upon the metabolism and growth of the cold-water coral Lophelia pertusa, collected from the Mingulay Reef Complex, Scotland, UK. Results from short-term exposure to increased temperature and pCO2 on freshly collected corals will be contrasted with current data from an ongoing 18-month experiment. Comparison of short and long-term data will help define the impact of ocean acidification and increased temperatures upon the growth, physiology and structural integrity of the reef framework forming coral Lophelia pertusa. GLOBAL OBSERVATIONS OF INTERNAL WAVES BY ARGO FLOATS
Internal waves are a significant contributor to deep ocean mixing, and consequently are likely a factor in ocean circulation and meridional overturning. We discuss here an analysis method that uses data from Argo floats equipped with Instrid communications. The method examines temperature measurements collected during the drift phase between vertical profiles, while the floats are parked at a quasi-isobaric stage. The combination of temperature stratification within the ocean and the vertical heaving of internal waves causes the temperature to vary at the parking depth of the float. The temperature variation is used to estimate internal wave displacement. Harmonic analysis of the displacement time series yields power spectra that are similar to the Garrett-Munk spectrum, with prominent tidal and inertial peaks. While Instrid floats do not yet provide comprehensive global coverage, the existing dataset is large enough in spatial extent to clearly identify a number of active and quiet regions for internal gravity waves in different ocean basins. EVALUATION OF A TRANSURANIC COMPONENT IN REACTOR DERIVED RELEASES FROM FUKUSHIMA DAI-ICHI TO THE MARINE ENVIRONMENT
The incident at Fukushima Dai-ichi on March 11, 2011 was the consequence of several events (earthquake, tsunami, equipment failures, etc.) and led to the release of radioactive contaminants into the atmosphere and ocean. Although the specific details regarding the mechanism and/or the extent of radioactivity released to the environment are lacking, significant levels of fission products such as 131I, 134Cs, and 137Cs have been observed in the vicinity of Fukushima. As part of a research cruise in June, 2011 to study the problem, we received water samples collected between 30 and 600 km offshore. The main objective of our work is to determine the presence of/characterize a transuranic component in the reactor releases. Specifically, we are in the process of evaluating the levels of 237 Np and Pu isotopes in samples from the cruise with a focus on the surface waters. Depending on the levels presented, the measured isotopic composition should be diagnostic in resolving reactor derived contamination from background levels associated with global fallout. We will report our findings and compare them to other available data sets. (Abstract ID 11572)

TEMPERATURE EFFECTS ON THE METABOLISM OF THE DEEP-SEA STONY CORAL, LOPHELIA PERTUSA
Lophelia pertusa was collected from the Gulf of Mexico. Oxygen consumption and metabolic enzyme activities were measured at 8°C (control), 11, 13, and 5 degrees Celsius. Activity of malate dehydrogenase (MDH) and citrate synthase (CS) were measured to determine aerobic capacity. Lactate dehydrogenase (LDH), an indicator of anaerobic poise, was undetectable. Oxygen consumption at 8 and 11 degrees were similar, averaging 4.14 and 3.30 ul. O2/polyph/b, respectively. At 13 degrees, respiration plummeted to 1.84 ul O2/polyph/b and half of the corals died. At 5 degrees, the temperature at which corals were held after collection, the lowest rate was observed, 1.17 ul O2/polyph/b. Despite this drop in metabolism, the corals seemed to adapt well to this temperature. CS averaged 0.13, 0.21, 0.09, and 0.14 units/g for the treatments at 8, 11.13 and 5 degrees, while MDH varied little at 1.79, 1.44, 1.48, and 1.55 units/g for the respective treatments. This study contributes much-needed knowledge about the basic biology of corals and their metabolic response to temperature, so that the effects of climate change can be elucidated on a physiological level. TOS/AGU/ASLO 2012 Ocean Sciences Meeting
NOAA’s Center for Operational Oceanographic Products and Services (CO-OPS) recently began measuring and disseminating visibility observations in coastal regions using forward scattering infrared sensors. Instrumentation was installed in response to requirements from the NOAA Physical Oceanographic Real-Time System (PORTS) partners for the main purpose of enabling safe navigation. Although CO-OPS previously participated in extensive visibility sensor testing to understand instrumentation, measuring and interpreting visibility along U.S. coasts is a new area for CO-OPS. In order to better understand processes of fog formation and to determine how relative humidity (RH) and solar irradiance measurements can be used to enhance visibility assessments, a field experiment is being conducted at a United States Army Corps of Engineers (USEACE) facility in Chesapeake City, MD. A test system consisting of visibility, RH, and solar sensors was deployed alongside an existing NOAA coastal water level station where wind and air and water temperatures are measured. The purpose is to analyze the relationships between visibility, RH, solar irradiance, and air/sea temperature gradients. Observations from the field experiment will be presented along with interpretation of results. (Abstract ID 12092)

DEcadal Variability in phytoplankton Populations in response to the North Atlantic Oscillation and Implications for organic carbon flux

Phytoplankton phenology and community structure is expected to change on interannual and decadal time scales in response to changing physical forcing, and to have subsequent impacts on ocean biogeochemistry. However, records of phytoplankton abundance are rarely long enough to address decadal variability – the exception is the Continuous Plankton Recorder dataset. Here we examine a time series of diatom and dinoflagellate abundance from 1958-2009 in the Northeast Atlantic, in the transition region between the subpolar and subtropical gyres. We find that in positive NAO periods, the region experiences subpolar-type conditions, with increased wind stress, deep mixed layers and enhanced upper ocean nutrient concentrations. In contrast, in negative NAO periods the region shifts towards more subtropical-like conditions. In response to negative NAO periods, not only is the phytoplankton bloom peak shifted one month later, but dinoflagellates are able to outcompete diatoms. The implications for carbon flux to the deep ocean are investigated using the Porcupine Abyssal Plain sediment trap time series data. Unexpectedly, the abundance of dinoflagellates is closely correlated with deep carbon flux, but abundance of diatoms is not. (Abstract ID 10986)

A MultiVARiate Analysis of observed and modeled Biophysical Variability on the Bering Sea Shelf: Multidecadal hindcasts (1969-2009) and Forecasts (2010-2040)

Coupled physical/biological models can be used to downscale global climate change to the ecology of subarctic regions, and to explore the bottom-up and top-down effects of that change on the spatial structure of subarctic ecosystems - for example, the relative dominance of large vs. small zooplankton in relation to ice cover. Here we utilize a multivariate statistical approach to extract the emergent properties of a coupled physical/biological hindcast of the Bering Sea for 40 years (1969-2009), which includes multiple episodes of warming and cooling (e.g. the recent cooling of 2003-2009). Specifically, we employ multivariate Empirical Orthogonal Function (EOF) analysis to derive the spatial covariance among physical and biological time series from our simulation. These are compared with EOFs derived from 1) spatially gridded measurements of the region, collected during the multi-year BASIS and BEST/BSERF field programs; 2) a midtidecadal regional forecast of the coupled models, driven by an IPCC global model forecast of 2010-2040. Insights into Seasonal Organic Carbon Cycling in the Delaware Estuary from n-Alkane Biomarkers and Stable Carbon Isotopes

Mixing across biogeochemical gradients in estuaries controls the geochemical reactivity and partitioning of marine and terrestrial organic carbon (OC). In the Delaware Estuary, urbanization and wetland sources further obscure OC pathways. Here, we show results from four axial surveys in four seasons (2010-2011) of water column particulate OC. Our bulk-δ13C values range from -30‰ upstream and -19‰ at the mouth, recording terrestrial inputs while tracking seasonal phytoplankton productivity in the lower estuary. However, bulk parameters lack sufficient sensitivity for OC source apportionment. n-Alkane biomarker patterns better delineate OC sources and show differences in OC inputs and transport between surface and bottom water samples. Export of terrestrial carbon from the estuary occurs in both surface and bottom water, but the depth of export varies with seasonal conditions. Mixed OC sources at the estuarine turbidity maximum (ETM) reinforce the importance of ETM for OC processing. Pronounced marsh n-alkanes suggest marsh-OC is a significant source of carbon within the Delaware Estuary. Thus, wetland OC may be important both geochronically and quantitatively for OC processing in the Delaware and other estuaries. (Abstract ID 9516)

A Ten-Year Plan to Build an End-to-End Regional Coastal Observing System (RCOOS) for the Southeast Region of the US

The Southeast Coastal Ocean Observing Regional Association (SECOORA) is one of eleven regional associations (RAs) that make up the U.S. Integrated Ocean Observing System (IOOS®). SECOORA covers coastal estuarine and ocean waters from North Carolina to the west coast of Florida. This region is vulnerable to storm hazards, potential impacts from oil drilling, and climate variability. SECOORA is building a RCOOS that integrates and augments existing observational, modeling, data management, educational, and scientific assets to improve our understanding of risks, improve decision making, reduce environmental and societal impacts, and support the economy of the region. This plan prioritizes user needs, leverages partnerships with other RA, federal and state agencies and stakeholders, and will improve data collection and accessibility. Improved decision support tools are also proposed within four themes: marine operations; coastal hazards; ecosystems, water quality; and living marine resources; and climate change. We present a regional plan that describes coastal, moored, and mobile monitoring assets build-out scenarios, and provides an integrated data management, modeling, product development, education and governance framework that assures the data collection assets are efficiently and effectively configured. Zooplankton, Micronekton and the Biological Pump: Beyond the Meso-scaleic Zone

Migrant biota transports carbon to the mesopelagic zone due to their feeding at the shallower layers and their defecation, respiration, excretion and mortality at depth. The so-called active flux has been considered a small number compared to gravitational sinking. Recent assessments in subtropical waters show an important effect due to predation by interzonal diel vertical migrants (DVMs). The consumption and subsequent transport of epipelagic zooplankton by DVMs (mainly micronekton) to the mesopelagic zone seemed similar to the mean gravitational export. However, the consequences of this active transport to the bathypelagic zone are almost unknown. Here, we show the effect of the Atlantic and Pacific equatorial upwelling systems on the vertical distribution of acoustic backscatter from the
surface to bathypelagic depths. The enhancement of the acoustic signal below the upwelling zone was observed to reach 4000 m depth, coinciding with high abundances and activity of bacteria at those depths. The results suggest an active carbon transport from the epipelagic driven by zooplankton and micronekton, enhancing the efficiency of the biological pump and giving an insight about the fate of an increased productivity at the shallower layers of the ocean. SPATIAL PATTERNS AND VARIABILITY THEREIN OF MICROBIAL POPULATIONS: AN ATLANTIC FIELD STUDY

In a seminal 1995 paper, Alan Longhurst divided the ocean into biogeochemical provinces using physical oceanographic processes and images from satellite observations. This partitioning has since been widely applied in a range of studies from carbon flux to zooplankton distributions. But how do these provinces relate to microbial plankton biogeography? These smallest planktonic organisms dominate primary production and are important drivers of biogeochemical cycles in the vast oligotrophic Atlantic. However, there is evidence that they are missed by remote sensing and it is still uncertain whether the marked mesoscale variability seen in their abundances in shelf seas also is a ubiquitous feature of the open ocean. Plankton surface samples were collected at 20 km resolution along an Atlantic Meridional Transect in May 2004, crossing five Longhurst defined provinces from the Fallland Islands to the British Isles. Nine microbial populations, including phototrophs and heterotrophs, were discriminated and enumerated by flow cytometry. A range of statistical analyses were used to assess the relationship between Longhurst provinces and microbial distributions, and to quantify mesoscale variability in populations within and between these provinces. A HIGH-RESOLUTION REGIONAL MODEL FOR THE BERING SEA ECOSYSTEM

The Bering Sea contains one of the most productive ecosystems in the world with significant social and economic implications. The ocean circulation in this region is complex with a broad range of spatial and temporal scales. In this presentation, we focus on the cross-shelf exchange processes explaining some of the dominant mechanisms controlling the dynamics of both physical and biological properties of the Bering shelf. We also present new data from an extensive survey of the shelf during the summers of 2010, 2011, and 2012. The new data support previous findings that the shelf waters in the Bering Sea are driven by the Kuroshio Extension, a strong, cold current that flows along the western coast of Alaska. The new data also indicate that the shelf waters are influenced by the Bering Front, a boundary between warm, saline water from the North Pacific and cold, fresh water from the Siberian Shelf. The new data provide a more complete picture of the physical and biological processes occurring on the Bering Shelf, and will be used to improve our understanding of the complex interactions between the physical and biological components of the Bering Sea ecosystem. WIND AND TIDAL INFLUENCES ON EXCHANGE IN A LARGE INVERSE ESTUARY IN WESTERN AUSTRALIA

The maintenance of a healthy estuarine environment depends on the ability of the system to exchange water with the ocean. In Shark Bay Western Australia, a large inverse estuary, gravity currents form during periods of reduced wind and tidal mixing. Field data from 2009 and numerical model results were used to predict an outflow event during the winter of 2011 and design a field experiment. The resulting measurements of current velocity and density profiles in the northern entrance channel showed that stratification and gravity currents were strong (up to 30 cm/s) and more persistent than previously estimated. Stratification in the deeper channels persisted even during periods of increased tidal mixing, and advection and mixing by intense wind events were important factors controlling exchange. The hydrodynamic model, validated by the field data, was then used as a tool to assess the relative importance of wind and tidal mixing. This work supports previous hypotheses that gravity currents are likely important for the larval dispersal of commercially fished scallop, prawn, and pink snapper. (Abstract ID 10948)

VIRAL DIVERSITY AND ECOLOGY IN AQUATIC METAZOA: EVIDENCE FOR VIRAL ROLES IN HOST MICROBIOMES

Viruses play important roles in pelagic and benthic compartments of aquatic habitats, contributing to the mortality of bacteria to whales. However, our knowledge of viral diversity in the oceans is limited. Metaviromics has proved a useful tool for investigating viruses associated with a variety of habitats, including metazoa. When combined with quantitative molecular approaches, this tool may provide insight into the ecology of discovered viruses amongst host populations. We recently have investigated viruses associated with several ecologically critical metazoa in both freshwater and marine habitats. Concomitant investigation of Daphnia population dynamics and the presence of two viral genotypes demonstrated patterns of prevalence and viral load consistent with potential population decline during summer 2011. Investigations into viral decay of several putatively metazoan viruses in lake waters and sediments suggest that these viruses may persist in aquatic habitats on longer timescales than native phage. Microscopic and genomic investigations of virus-like particles and genomes in echinoderms (urchins, sea stars and sand dollars) and the dogfish Squalus acantius demonstrate the unexpected presence of viruses in healthy populations of metazoa. Our data suggest that viruses may occur as components of multi-kingdom host microbiomes, and that there is much to be learned about the diversity and dynamics of viruses in aquatic metazoan populations. ALONGCOAST STRUCTURE OF SEASONAL WATER PROPERTIES AND VELOCITY ON THE NORTHERN CALIFORNIA CURRENT SHELF

Moored sensors were maintained for five years in an alongshelf array spanning ~60 km. The array included a location strongly influenced by the Columbia River year round (Grays Harbor, Washington); central Oregon (Newport); and sites just north (Coos Bay) and just south of a coastal promontory, Cape Blanco, where the equatorward coastal jet frequently separates from the shelf (Rogue River). In spite of the local environment and physical and physical differences, seasonal cycles in salinity and temperature were very similar in magnitude below a depth of about 10 m. However, south to north seasonal lags of 1-2 months in T/S extrema were observed over the array. Properties of water upwelled onto the shelf in summer were similar over the array and
displayed no memory of properties from the preceding winter; the latter had a much greater degree of site to site variability. In contrast to water properties, velocity in the summertime equatorward jet had significant alongshore structure. Maximum equatorward flow in spring/summer precedes local upwelling-favorable wind stress (~1 month) and the occurrence of coldest, saltiest water (~2 months) at all locations. (Abstract ID 10867)

Adaptive meshes as a tool for submesoscale ocean modeling

Adaptive mesh models aim to efficiently simulate transient and complex multi-scale processes by dynamically adjusting mesh resolution. The utility of adaptive meshes, as implemented in Fluidity-ICON [1], for submesoscale ocean modeling is assessed by evaluation of simulations of the lock-exchange. This simple set-up incorporates diverse processes, including gravity currents, internal waves and turbulence, that all enhance the mixing.

The Froude number (non-dimensional gravity current front speed) and background potential energy (a measure of the mixing) are used to evaluate the performance of fixed and adaptive meshes. The adaptive mesh simulations produce comparable values of the diagnostics to the higher resolution fixed mesh simulations whilst using at least one order of magnitude fewer nodes. The results also compare well with published values, e.g. [2] [3]. The choice of metric, which guides the mesh adapt, is shown to be crucial for good representation of the dynamics. The accurate and efficient modeling of the flow and mixing at varying scales offers a promising outlook for the use of adaptive meshes in submesoscale ocean modeling.

Differential Effects of Ocean Acidification on Calcification of Algal-Symbiont Larger Rentic Foraminifers

Ocean acidification, which is an outcome of anthropogenic CO2 as well as global warming, may have a severe impact on marine calcifying organisms, especially those living in coral reef ecosystems. Here we show results of a series of culture experiments on two groups of algal symbiont-bearing, reef-dwelling foraminifers, Amphisorus kudakajimensis and Calcarina gaudichaudii, in acidified seawater prepared with a precise CO2-bubbling technique. While A. kudakajimensis showed a reduced net calcification with higher pCO2 conditions, calcification of C. gaudichaudii was generally increased as pCO2 elevated. In another culture experiment conducted in seawater in which bicarbonate ion concentrations were varied under constant pCO2 conditions, calcification of C. gaudichaudii was generally increased as pCO2 elevated. In another culture experiment conducted in seawater in which bicarbonate ion concentrations were varied under constant pCO2 conditions, calcification of C. gaudichaudii was generally increased as pCO2 elevated. From these results, we concluded that carbonate ion and CO2 were the carbonate species that most affected growth of Amphisorus and Calcarina, respectively. The opposite responses of these two foraminifer genera probably reflect different sensitivities to these carbonate species, which may be due to their different symbiotic algae. (Abstract ID 11205)

Particle Composition and the Area-to-Mass Ratio of Suspended Marine Particles

The accurate conversion of an optical signal into suspended sediment mass depends on an accurate estimate of the ratio of particle cross-sectional area to particle mass. This ratio has been observed to vary over an order of magnitude among many field studies. Historically, the variability has been attributed to particle size, but recent work shows that, because marine particles are aggregated, size only accounts for about a factor of 2 variability in the ratio. Therefore, component particle composition and particle packing within aggregates must account for a significant fraction of the observed variability in the area-to-mass ratio. With data from coastal waters around the west coast of the United Kingdom, we examine the hypothesis that composition accounts for only a factor of 2 variability in the area-to-mass ratio. When all data are considered together, the hypothesis receives support. Removal of apparently anomalous data from a single site, however, suggests that the organic fraction in suspension has a significantly greater effect on the area-to-mass ratio. This result suggests that particle composition and particle packing within aggregates are correlated. (Abstract ID 9936)

Interrelated Influence of Ni and Light on Trichodesmium Growth

Nitrogen fixation in the ocean influences global biogeochemical cycles of nitrogen and carbon. Understanding how nitrogen fixation is regulated in the oceans may shed light on mechanisms controlling carbon dioxide cycling and climate change globally. Trichodesmium, the primary diazotrophic phytoplankton in tropical and subtropical oceans, accounts for half of new production in the oceanic regions. Our previous study demonstrates that Ni availability can control cellular superoxide dismutase activity and nitrogen fixation rates, suggesting that the enzyme may be involved in the protection of nitrogenase from superoxide radical inhibition during photosynthesis in the non-heterocystous diazotroph. In this study, we further demonstrate that the interrelated influence of Ni availability and light intensity can either limit or sustain Trichodesmium growth. The growth of the cells is inhibited under high light and low Ni conditions. Relatively, sufficient Ni supply sustains the elevated growth of Trichodesmium under high light conditions. This finding exhibits major implications for interpreting spatial distributions and activities of Trichodesmium, and for the existing models of mechanistic controls on nitrogen fixation in modern and ancient oceans when and where Ni availability and light intensity have varied. (Abstract ID 10145)

TESTING A NEW TECHNOLOGY FOR BIVALVE LARVAE IDENTIFICATION

Identification of bivalve larvae is challenging due to their small size. A new technique using polarized light may revolutionize the way bivalve larvae are classified. It is based on the understanding that bivalves build their shells out of calcium carbonate and lay down crystals in species-specific patterns. This technique has shown to be highly accurate using larvae grown under controlled conditions, but previous studies revealed that field conditions increased error in larval recognition (Thompson 2011). In this study, the oyster, Crassostrea virginica, was raised under different conditions of temperature, salinity, and food concentration to test whether growth conditions affect the accuracy of the polarized light analysis. Our results indicate that differences in growth conditions do affect the accuracy of the technique. In addition, we found that the technique had the highest accuracy (86%) when image training sets included larvae reared in multiple growth conditions. (Abstract ID 10529)

ACID AND PHENYLALANINE IN PRIMARY PRODUCERS AND Δ, THE 15N ENRICHMENT AT EACH TROPHIC STEP

The Monterey Bay Aquarium Research Institute (MBARI) has developed a new long range AUV called Tethys. In a little over a year of science field operations the first vehicle has logged over 2000 hours of operations during mostly 7 day long deployments using rechargeable batteries. The vehicle is currently at sea with a set of primary batteries and is two weeks into a three week experiment that extends 500 km offshore. Interactions with the vehicle at sea are accomplished via a web interface which displays science and engineering data and allows the operator to modify mission parameters or even start new missions. The core science payload measures the temperature, salinity, dissolved oxygen, nitrogen, chlorophyll and two channels of backscatter. A turbulence sensor and an AUV Docking payload have been built and there are plans for additional payload in the extendable flooded nose section. (Abstract ID 12517)

KELVIN-HELMHOLTZ OVERTURN BOUNDARY IN VISCOS FLOWS

Shear instability in stratified flow is explored using two- and three-dimensional numerical simulations of the Boussinesq equations. There is a region in Richardson-Reynolds number space where the Kelvin-Helmholtz instability grows but is dissipated before it can significantly change the mixing dynamics. The appearance of density overturns is used to distinguish mixing regimes as a function of Reynolds and Richardson numbers. An approximate criterion for this overturning in terms of initial Richardson and Reynolds number is proposed and compared with the numerical results. Initial conditions use perturbations of the Kolmogorov scale for the initial shear flow. Linear stability analysis of the flow is used to help characterize the viscous instability. COMPOND SPECIFIC ISOPTE ANALYSIS IN FOOD WEB STUDIES: THE NEED FOR ACCURATE ESTIMATES OF TROPHIC ENRICHMENT FACTORS

Ecosystem-oriented fisheries management strategies require knowledge of trophic relationships. Trophic position (TP) estimates from compound specific nitrogen isotopic analysis of amino acids (AA-CSIA), although promising, have not been thoroughly tested. TP estimates from AA-CSIA require knowledge of the difference in 15N values between glutamic acid and phenylalanine in primary producers and the 15N enrichment at each trophic step or trophic factor enrichment. Values of 0.7‰ and 7.6‰ have been suggested for aquatic environments, however recent observations indicate that Δ may be variable particularly or trophic enrichment factor. Values of β (3.4‰) and ∆ (7.6‰) have been suggested for aquatic environments. (Abstract ID 11921)

A 2003 REANALYSIS OF THE CHESAPEAKE BAY USING SATELLITE AND IN SITU DATA

An advanced data assimilation system has been set up for the Chesapeake Bay using the local ensemble transform Kalman filter (LETKF) and a ROMS model of the Bay (ChesROMS). Errors in wind forcing dominate the chaotic growth of initial condition errors, but using an ensemble of forcing fields as well as adaptive inflation techniques these errors are managed. We will show results from the assimilation of real SST from NOAA’s AVHRR instrument and in situ temperature and salinity profiles. Performance is evaluated for the year 2003 as both dependent and independent in situ observations of temperature and salinity. We also investigate the nature of the flow changes made by the assimilation. (Abstract ID 11908)

THE CIRCULATION OF THE MIDDLE ATLANTIC BIGHT (MAB) AND DELAWARE BAY ON THE US EAST COAST WAS SIMULATED USING A VERSION OF THE REGIONAL OCEAN MODELING SYSTEM CONFIGURED FOR THOSE AREAS. WATER FOLLOWING LAGRANGIAN PARTICLES RELEASED IN THE CIRCULATION FIELDS SIMULATED THE GROWTH AND Vertical MIGRATION IN RESPONSE TO FOOD, TEMPERATURE AND salinity FOR LARVAL OYSTERS (CRASSOSTRANGIDENTA) IN DELAWARE BAY AND ATLANTIC SALMON SMOLTS (SALMO SISALISSINUS) IN THE MAB. THE LARVAL PARTICLES WERE TRACKED UNTIL THEY REACHED SETTLEMENT SIZE. THE OYSTER LARVAL SIMULATIONS SHOWED THAT ORITENIC VERTICAL MIGRATION behavior resulted in shorter dispersal scales which favored larval settlement in areas with major oyster reefs. THE SURF CLAM LARVAL SIMULATIONS SHOWED THAT behavior reduced the total transport distance and retained the larvae in inner shelf regions. FOR BOTH AREAS VARIABILITY IN ENVIRONMENTAL CONDITIONS PLACED STRONG CONTROLS ON LARVAL SURVIVAL. THESE COUPLED CIRCULATION-LARVAL MODELS ALLOWED EVALUATION OF CONNECTIVITY AND GENETIC EXCHANGES IN OYSTER AND SURF CLAM POPULATIONS
and investigation of changes that may occur in larval dispersal patterns and settlement areas as a result of climate change. (Abstract ID 11452)

Hofmann, G. E., UC Santa Barbara, Santa Barbara, USA, hofmann@lifesci.ucsb.edu

Elevated pCO2 (Ωarag ~ 0.8) was roughly 8%; however, present conditions for Antarctic larvae are more divergent coastal regions: a temperate upwelling site in California, and an Antarctic site. These physical data were coupled with manipulative laboratory experiments using larval-stages of sea urchins from these two regions; these experiments tested species responses to environmentally relevant fluctuations in ocean pH to identify risk from future ocean acidification. Various performance metrics suggest that development is quite resilient in the species tested; for example, length differences between larvae of both species at control pCO2 were consistently the most abundant class in the largest size fraction of the DCM until the transition to the furthest offshore SCM where Gamma proteobacteria dominated. Gene abundance data demonstrate a widely distributed potential for microbial assimilation of low-molecular weight compounds in all sampled size fractions and ecological regimes. Positive correlations between the abundance of genes coding for the active transport of high-molecular weight iron complexes and increasing size fraction suggest that organically complex iron may be an important resource for particle-associated bacteria. Our data highlight prokaryotic assemblages, particularly those in SCM, with strong potential for internal recycling of nutrient elements. (Abstract ID 12247)

Holbrook, W. S., University of Wyoming, Laramie, USA, steveholbrook@uwyo.edu

The South China Sea (SCS) hosts large-amplitude, non-linear internal waves (NLW) that originate via poorly-understood processes at bathymetric ridges in the Luzon Passage. We present new images of thermohaline finestructure in the SCS and Luzon Passage from a seismic (plus XBT) cruise conducted by R/V Langseth in summer 2009, which may shed light on the generation mechanisms of NLW. We image several clear sets of NLW in the SCS, down to depths of about 1200 m. Wave amplitudes are up to 75 m, and the vertical wave heights are consistent with a mode-1 wave. Horizontal wavelengths are much shorter (~400 m) in the upper 200 m of the wave, in contrast to deeper depths, where wavelengths are between 1-2 km. Near the ridge, clear changes occur in patterns of finestructure; within ~30 km of the ridge, long, continuous reflections become progressively disrupted and reflector displacements become higher. Reflector slope spectra show evidence of enhanced internal wave energy and turbulence near the ridge. Comparisons to a numerical model of isopycnal displacement show strong turbulence during times of peak tidal displacement. (Abstract ID 12674)

Hofmann, J., Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, jens.hofmann@awi.de

The Lena River strongly influences physical, biological and chemical processes on the Laptev Sea shelf through vast amounts of freshwater runoff. The Lena river water is poor in nutrients and carries high concentrations of dissolved organic matter (DOM) and colored dissolved organic matter (CDOM). Here we present CDOM absorption complemented by profiles obtained with an in situ WETStar fluorometer during expeditions in August 2010 and 2011, in order to study the vertical and horizontal CDOM distribution on this shelf. The results show that the river Lena dominates the supply of CDOM which exhibits a conservative mixing behavior over a wide range of salinities. The low light penetration of the CDOM rich river water in conjunction with low concentrations of dissolved phosphate and nitrate and a strong density stratification of the water column result in low chlorophyll a concentrations within and beneath the river plume. Outside of the river plume increased water transparency and the
upward transport of phosphate and nitrate from nutrient enriched bottom waters lead to the formation of deep chlorophyll maxima at the pycnocline. (Abstract ID 9514)

DEPOSITION, DISTRIBUTION AND FATE OF MACONDO OIL IN THE SEDIMENTS OF THE NORTHEASTERN GULF OF MEXICO

Blowout of BP’s Deepwater Horizon drill-rig in the northern Gulf of Mexico resulted in an expansive surface oil layer and the formation of toxic subsurface oil plumes. High-resolution imaging, compositional and sedimentological analyses of sediment cores collected in the region of the oil spill show fundamental changes in the contemporary sedimentary processes with the deposition and accumulation of laminated, organic-rich, fine-grained surface sedimentary layers, particularly in the DeSoto Canyon region. Down-core analyses of short-lived radioisotopes document a dramatic thickening of the post-blowout surface-layer (up to 6 cm) and a >10-fold increases in mass accumulation rates relative to pre-blowout conditions. High-resolution molecular organic geochemical analyses of the post-blowout surface-sediments reveal spatial variability with petroleum derived hydrocarbon deposition occurring in three modes: as almost pure horizons, in direct association with algal, terrestrial plant and bacterial biomass, and as a minor component mixed with terrestrial plant waxes. Multiple mechanisms of oil-sediment deposition including: 1) a toxic-bath tub ring, 2) a flocculent blizzard and 3) an open flood-gate must be invoked. Benthic ecosystem impacts are discussed. TRANSIENT DISPERSIVE PROCESSES IN CHANNEL-SHOAL ESTUARIES

Dispersive processes in estuaries are often modeled as Fickian diffusion, with assumptions of complete lateral mixing and linear growth of the second central moment. We investigate scalar plumes in a channel-shoal estuary, focusing on transient dispersive processes during the period before lateral homogenization can be assumed. For wide estuaries, with scalar sources and sinks away from the head or mouth, this is an important period as in many cases a plume never mixes completely shore to shore. Residual circulation, tidal stirring and turbulent mixing vie for dominance in determining the relationship between lateral mixing time and residence time. Regimes of transient dispersion include Taylor dispersion and unbounded shear dispersion. Idealized simulations are used to characterize how estuary length, width, channel-shoal bathymetry and tidal phasing assert control over the timescales of lateral mixing and residence time. Extending to sediment transport, we examine the difference in dispersion when settling and resuspension are taken into account. Applied to South San Francisco Bay we find that the norm is not Fickian diffusion but instead to semi-bounded shear dispersion with quadratic variance growth. (Abstract ID 11517)

REDUCTION IN ARCTIC OCEAN FRESHWATER EXPORT

The changing nature of the export of freshwater from the Arctic to the North Atlantic subpolar gyre is explored. Freshwater is critical to the restraint of dense water formation via its capacity to ‘cap’ ocean convection, and, through control of Labrador Sea dynamic height, has a profound effect on the circulation intensity and zonal extent of the subpolar gyre. Changes in Arctic outflows could therefore disturb the dynamics of the subpolar gyre and the global thermohaline circulation. We examine evidence from two independent high resolution oceanographic models (NEMO-ORCA205 and OCCAM 1/12), salinity measurements on the Labrador and Newfoundland shelves, and a hydrographic survey in late summer 2008. We show that the model results are consistent with measurements from moored current meter arrays, and that freshwater storage in the Arctic. The evidence consistently supports the hypothesis that Arctic freshwater export decreased west of Greenland from the 1990s to 2008. During this period the Arctic Ocean was storing freshwater in the upper layer; we show that the cumulative reduction in export could account for most of the observed increase in storage. TRADE-OFFS ASSOCIATED WITH MODELING FISH AND SHELLFISH RESPONSES TO CLIMATE CHANGE IN GLOBAL CLIMATE MODELS OR EARTH SYSTEMS MODELS

The marine science community has embarked upon an effort to project climate change impacts on marine ecosystems and the responses of fishery dependent communities to these ecosystem changes. Considerable progress has already been made in coupling nutrient, phytoplankton and zooplankton into physical models using the existing Global Climate Model and Earth System Models. There is considerable interest in extending this capability to include commercially exploited fish and shellfish. Fish and shellfish exhibit complex responses to changes in the distribution and abundance of prey, competitors and predators. Incorporation of these complex processes will come at a high computational cost. This paper compares the costs and benefits of different methods for modeling fish and shellfish responses to climate change on a global scale. A variety of different modeling approaches are considered including: minimally realistic tropic energy transfers, size spectrum models, single species and multispecies stock assessment models, whole ecosystem food web models, spatially explicit coupled-biophysical models (e.g. NEMURO-FISH), and spatially explicit gradient tracking models. OPTICAL ESTIMATION OF THE FRACTION OF BREAKING WAVES

Dissipation of incident waves in the surf zone affects not only the energy balances but also momentum budgets through radiation stress gradients that force nearshore circulation. In 1978, Battjes and Janssen suggested that the dissipation of a single depth-limited breaker should scale with depth so that the total dissipation just depends on this time the probability of breaking, the so-called fraction of breaking waves, Q_b. This is the form used in the wave model SWAN, but Q_b is a model product rather than an observable input. Since breaking waves have strong optical signatures, our goal is to develop and test a method for directly measuring Q_b from optical data. Breakers are identified by a sharp increase in reflectance, detected using standard edge detection methods in space-time data from cross-shore transects of optical data (Argus time stacks). Stacks are first adjusted using chlorophyll estimates to remove wave propagation delay. Methods were tested using data from the Surf Zone Optics experiment at Duck, NC in September, 2010. DUST FERTILIZATION OF THE WESTERN ATLANTIC BIOTA: A BIOCHEMICAL MODEL

Every year an estimated 50 million tons of African dust reaches the Western Atlantic. This dust is composed of quartz sand, clay, and a mixture of quartz and clay particles agglutinated with micronutrient enriched ferruginous cement. However, whether it is friend or foe to biochemical systems is a matter of conjecture. Corals are ideal recorders of changing conditions, as the layers can be dated so that the record of chemical changes is easily assessed. There is every reason to believe that the coral reef is a recorder of the history of the dust and its effects on the environment. Corals are complex organisms that have strong optical signatures, our goal is to develop and test a method for directly measuring Q_b from optical data. Breakers are identified by a sharp increase in reflectance, detected using standard edge detection methods in space-time data from cross-shore transects of optical data (Argus time stacks). Stacks are first adjusted using chlorophyll estimates to remove wave propagation delay. Methods were tested using data from the Surf Zone Optics experiment at Duck, NC in September, 2010. AIRBORNE SAR RAPID-REPEAT OBSERVATIONS OF SMALL-SCALE EDDIES OBTAINED DURING THE SUBMESOSCALE EXPERIMENT-1 IN THE SOUTHERN CALIFORNIA BIGHT

Repetitive observations of small eddies were obtained on April 14-16, 2011, by NASA's UAVSAR aircraft system, coincident in time and aircraft optical observations being collected during the NASA-supported Submesoscale Experiment-1 (SubEx1). This experiment was designed to improve the understanding of eddy dynamics and energetics with a unique combination of in situ, aircraft, and satellite observations. The experiment took place north of Catalina Island in the Southern California Bight, an area known to have extensive small-scale eddies. Small-scale eddies are detected by SAR in coastal environments by the appearance of surface features, which act as tracers of the underlying current field. Multiple repeat SAR observations were obtained approximately on hourly intervals that enable the tracking of the rapidly evolving eddy field and derivation of rotation velocity maps through feature tracking. This study will present preliminary results of eddy tracking from this fine resolution (5m) aircraft SAR, and an interpretation of the surface features when compared with coincident high-resolution ocean surface temperatures, measured through airborne infrared observations, and in situ temperature transects. STRUCTURE, PROPERTIES, AND HEAT CONTENT OF EDDIES IN THE SOUTHEAST PACIFIC OCEAN

The southeast Pacific (SEP) requires an input of cold water to balance solar heating. One potential source is the offshore transport of cool, coastal waters by eddies. In this study, a variety of observations were used to estimate the effect of eddy transport on upper-ocean temperature in the SEP. Data from the VOCALS-REx field program were used to characterize eddy structure. Cyclonic (anticyclonic) eddies possessed shoaling (depressed) isopycnals, shallow (deep) salinity minimum layers, and high (low) stratification beneath the mixed layer. An intensively surveyed cyclonic eddy had a salty and highly stratified anomaly along the 26.5 °C isotherm. The Southern Ocean locations have little vertical structure, with a −1°C at 100m depth. A relationship between sea level anomaly and upper-ocean temperature transects. (Abstract ID 9895)

IMPROVED CONSTRAINTS ON TRANSIT TIME DISTRIBUTIONS FROM ARGON 39: A MAXIMUM ENTROPY APPROACH

We use Ar-39 in conjunction with CFCs, natural C-14, PO4*, temperature, and salinity to estimate the ocean’s transit time distributions (TTDs). A maximum entropy approach is employed to deconvolve the tracer data for the TTDs. The constraint provided by Ar-39 allows us to estimate TTDs even in the deep Pacific where CFCs have not yet penetrated. From the TTDs, we calculate the ideal mean age, the TTD width, and the mass fraction of water with transit times less than a century. We also quantify the uncertainties due to the nonuniformities of the deconvolutions. In the Atlantic, the patterns of T and reflect the distribution of the major water masses. At the deepest locations in the Atlantic (T = 300–500°C), while at the deepest locations in the Southern Ocean (T = 500–1000°C). The Pacific is nearly homogeneous below 2000m with T = 1300–2000°C. In the North Pacific and T = 900–200°C, a in the deep S Pacific. The Southern Ocean locations have little vertical structure, with T = 300 to 450°C with an uncertainty of about +150 to 40°C. The importance of eddy diffusion compared to advection as quantified by ΔT has most probable values ranging from 0.2 to 3 but with large uncertainty bounds ranging from 0.2 to 9. For most locations analyzed, the effect of Ar-39 is to reduce f and to correspondingly increase by about a century. Ar-39 reduces the uncertainties of f by ~50%. (Abstract ID 10901)

THE ISOTOPE COMPOSITION AND FLUX OF ION FROM MARINE SEDIMENTS TO THE EASTERN SOUTH ATLANTIC (GEOTRACES A10)

Sediment pore waters collected from 6 Stations between 18°E and 5°W in an E-W transect of the South Atlantic Ocean (GEOTRACES transect A10), have been characterized for diagenetic reactions of oxygen, nitrate, Fe and Mn, and a range of redox gradients are observed. South African shelf-slope sediments (700-1100 m water depth) intersect the oxygen minimum within Upper Circumpolar Deep Water (~170-200 µM) in this region, and oxygen penetration depths are correspondingly shallow (<1 cmbls) compared with shallower shelf-top (236 m), deeper shelf-slope (2002 m) or Cape Basin sediments (~4000-5200 m) under more oxygenated bottom waters. Diffusion-reaction modeling of pore water Fe and O2 data indicates that the thin oxygenated surface layer overlying dissolved Fe maxima (up to 6 µM) on shelf-slope sites contributes ~0.1-0.3 µmol Fe m−2 d−1 to bottom waters in this region, with implications for the bioavailable inventory of dissolved Fe in this region. We also present the isotope composition of Fe in the pore waters to constrain the Fe isotope supply from Cape margin sediments to South Atlantic seawater and refine tracer studies of benthic Fe sources. DETERMINING SEAFLOOR COMPOSITION THROUGH MULTIBEAM SONAR

A study conducted in the Triple Junction Area of Puget Sound over October 17-18, 2011 used EM302 Multibeam Sonar data to map not only the bathymetry of the seafloor, but also to determine the basic seafloor composition. Advantages of using multibeam rather than singlebeam bathymetry include extremely high resolution data covering a larger study area. By assessing both rate and intensity of return from sonar beams, one can distinguish seafloor solidity (the more solid the composition, the greater the intensity of the return). Combining sonar data with groundtruth samples (Van Veen grabs), we can associate individual beam intensity to a corresponding seafloor category (rock, gravel, sand, or mud). These categories can then be correlated with seafloor bathymetry to produce a more comprehensive map than one strictly showing bathymetry. Mapping seafloor composition is useful in the Puget Sound area to help understand the influences of urbanization on the seafloor; show the composition of erosional features, and assist in understanding bathymetric patterns. If studies are conducted over longer temporal scales, this method can also be used to study changes in seafloor composition, which can help provide insight into anthropogenic influences in the estuary. DIFFUSION OF ARTIFICIAL CAESIUM-134 AND -137 IN THE WESTERN NORTH PACIFIC ONE MONTH AFTER THE FUKUSHIMA ACCIDENT

In March 2011, an accident at the Fukushima Daiichi nuclear power plant (FNPP) was caused by the Tohoku earthquake and tsunami. Here we show the distribution of artificial caesium-134 and -137 (134Cs and 137Cs) in the western North Pacific Ocean one month after the FNPP accident. In surface seawater, 137Cs concentrations were from several times to two orders of magnitude lower than before the FNPP accident. 134Cs was also detected, and in many seawater samples the 134Cs/137Cs ratio was about 1. These findings indicate that radionuclides from the FNPP dispersed quickly in the western North Pacific. 134Cs and 137Cs concentrations in suspended particulate matter were much lower than before the accident. Numerical simulation results show that the higher caesium observed in the western North Pacific one month after the FNPP accident was transported not only by diffusion and advection of seawater but also via the atmospheric as an aerosol. We also compare the surface currents to concurrent vertical current profiles of a bottom UHF radar system. The land-based installation collected observations of radial surface current data collected from October 10 to December 11, 2010 using a RiverSonde (CODAR) their accuracy is often hindered by the limited tidal current observations available for validation.

Hague, C. C., CODAR Ocean Sensors, Ltd., Mountain View, USA, cal@codar.com

REMOTE OBSERVATIONS OF SURFACE CURRENT STRUCTURE AT AN ENGINEERED TIDAL INLET MOUTH

An understanding of physical and ecological communication between ocean and estuary is vital for predicting pollutant dispersal, fishery protection, and harbor entrance safety. While numerical models can simulate the governing circulation processes at inlet mouths, evaluating their accuracy is often hindered by the limited tidal current observations available for validation. Surface currents measured by remote sensing devices are a relatively new option, providing long term, continuous data that can span the width of the inlet mouth. Here we present surface current data collected from October 10 to December 11, 2010 using a RiverSonde (CODAR) UHF radar system. The land-based installation collected observations of radial surface current components over an 800 by 400 meter footprint at 7.5 meter range and 1 degree azimuthal grid spacing between the jetties at the mouth of Yaquina Bay (Newport, Oregon) every 5 minutes. We also compare the surface currents to concurrent vertical current profiles of a bottom mounted ADCP located within the radar footprint, and examine the spatial structure of the surface currents and its dependence on the tidal forcing and freshwater estuarine inputs. ARRIVAL OF RADIOESCIUM FROM THE DAMAGED FUKUSHIMA DAI-ICHI NUCLEAR REACTORS OF IN THE SEAS LOCATED IN THE WEST OF FUKUSHIMA

Korean Peninsula is located about 1,000 km westward from Honshu Island of Japan. Radioiodides started to be released on March 12 into the atmosphere from the damaged reactors in Fukushima, eastern coast of Honshu Island. Radioiodines appeared to arrive over the Korean Peninsula first on March 24 and the atmospheric activity concentrations of 134Cs and 137Cs peaked around April 7 and subsequently decreased toward the end of April with occasionally detected in the early May. The Fukushima originated radioiodines appeared to be largely arrived in Korea from the west rather than the east due to the prevailing westerlies at that time. The seas adjacent to Korean Peninsula, Yellow Sea, Korea Strait, and the East Sea (Sea of Japan) were monitored from March 30 to June 8. 134Cs and 137Cs in the surface waters were found to be 0.11 - 1.19 and 1.3 - 3.0 mbq/kg, respectively. The 134Cs were detected on March 29 and increased to April 8 in the Korea Strait, probably reflecting the temporal atmospheric 134Cs concentration peak. The activity ratios between 134Cs/137Cs were 0.1~0.5. Samples are still being measured and we will report our findings in relation to the earlier measurements in the seas to Korean Peninsula at the meeting. (Abstract ID 11038)

SPECIES SPECIFIC VARIATIONS IN COPEPOD GRAZING BEHAVIOR RESULTING FROM EXPOSURE TOXIC DINOFLAGELLATE

Our objective is to quantify the behavioral response of copepods to varying diets, in particular when they are exposed to toxic dinoflagellates. The conjectured role of toxins as grazing deterrents is investigated using digital holography to compare the behavior of Acartia tonsa on nutritional Storeatula major to that occurring during exposure to toxic and non-toxic Karenia brevis and Karlodinium veneficum. Analysis of the feeding appendage beating duration enables us to distinguish between two beating modes with lognormal distributions: short duration “sampling beating” with little fluid entrainment, and longer period “grazing beating” that generates feeding currents. Without prey, A. tonsa only samples water infrequently, and upon introduction of desired food, it increases the grazing substantially. On mono-algal diets of toxic dinoflagellates, sampling durations are high, but grazing remains low. In mixtures of S. major and toxic K. brevis, sampling and grazing both diminish, presumably due to neurological effects of consuming brevetoxins during attempts to prey on S. major. In contrast, both modes persist during A. tonsa exposure to mixtures of toxic K. veneficum, indicating that karlotoxins do not inhibit grazing. (Abstract ID 11582)

A GLOBAL, EDDYING, DYNAMICALLY-CONSISTENT, OCEAN AND SEA ICE STATE ESTIMATE OBTAINED USING ADJOINT METHOD

As part of the Estimating the Circulation and Climate of the Ocean, Phase II (ECCO2) project, a two-year (January 2009 to December 2010), eddy-permitting ocean and sea ice state estimate has been obtained using the adjoint method. The model is a cubed-sphere configuration of the Massachusetts Institute of Technology general circulation model (MITgcm) with 18-km horizontal grid spacing and 50 vertical levels. The data constraints include AMSR-E SST, OSTM almsterr, and ARGO temperature and salinity profiles. The control parameters include the temperature and salinity initial conditions and the time-evolving surface atmospheric state. At time of abstract submission, 23 forward-adjoint minimization steps have been completed and the overal cost function has been reduced by approximately 57% relative to the baseline integration, with significant improvements relative to data in the mean stratification of the solution as well as in the variability relative to almsterr and SST data. This presentation will show details of this minimization and assess this solution versus a variety of metrics established by the CLIVAR Global Synthesis and Observations Panel. (Abstract ID 12264)

MODELING EMERGENT MICROBIAL COMMUNITY STRUCTURE AND BIOGEOCHEMICAL CYCLING IN THE AMAZON RIVER AND PLUME

The Amazon River has the largest drainage basin in the world, about 7,050,000 square kilometers, and it accounts for approximately one-fifth of the world’s total river flow. It carries commensurately large nutrient, sediment and organic matter loads, which include a rich microbial community that is dominated by heterotrophic organisms that require under oxygen replete conditions. In this paper we present the first results from a genomics-based emergent properties model that simulates changes in the composition of the microbial community and their impact on biogeochemical cycling in the Amazon River as water flows down the lower reaches and out into the plume in the Atlantic Ocean. Due to the rapid transport in the river the microbial community composition and nutrient concentrations do not change dramatically as the water flows downstream except where there are substantial lateral tributary inputs and exchanges with flooded surrounding forests. Dramatic changes are also driven by mixing between fresh and saltwater microbial communities in the plume. Efforts to validate the model with genomic data are presented. (Abstract ID 12063)

EXPERIMENTAL INVESTIGATION OF TURBULENCE AND SUSPENDED SEDIMENT IN THE WAVE BOTTOM BOUNDARY LAYER

Sediment resuspension due to waves is an important mechanism for sediment transport in lakes and continental shelves, supporting gravity driven flows of high concentration muds. Models describing wave generation of suspension layers typically invoke a balance between turbulence and suspended sediment concentration, resulting in a fixed Richardson number. However, due to the thinness of the wave boundary layer and the episodic nature of waves, these models are difficult to test in the field.

We present results from a series of laboratory experiments conducted in a U-tube wave tank that resolve the turbulent structure of the wave boundary layer in high sediment concentration flows. We use a Fiber Optical Backscattering array, multi-beam Acoustic backscatter and a profiling ADV to make very high resolution co-located measurements of suspended-sediment concentration and velocity over a range of wave conditions and bed slopes typical of the continental shelf. We present a detailed phase-averaged description of the turbulence and sediment transport processes within and just above the wave boundary layer, particularly TKE budget and the effect of suspended sediment concentration on it. We observe the wave boundary layer is transitionally turbulent, developing as a laminar boundary layer after wave resuspension, and becoming turbulent after the transition to minimum turbulence. The results are also compared favorably with a time-varying eddy viscosity model. (Abstract ID 11845)

THE GELATINOUS ZOOPLANKTON COMMUNITIES OF GODTHÅBSFJORDEN, WEST GREENLAND

We conducted a survey of the composition, abundance, and distribution of non-copepod groups along a transect leading from the furthest inland extend of Godthåbsfjorden into the offshore waters of Fylas Bank, West Greenland. Gelatinous zooplankton were identified and measured on unpreserved material with the aid of a light table. In total we collected 17 species of hydrocladus, 2 species of siphonophores, 3 species of scyphomedusae, 3 species of ctenophore, 5 species of chaetognaths, 1 species of pteropods, 1 species of pelagic polychaete, 2 species of hydromedusae, 2 species of siphonophores, 3 species of scyphomedusae, 3 species of appendicularians, for a total of 36 species. Ctenophores were unexpectedly abundant during the cruise with Fylas Bank communities dominated by the ctenophore Mertensia ovum, with lesser contributions by Bolinopsis infundibulum. Inside the fjord, Mertensia abundance declined precipitously with the community becoming dominated by at least 2 species of Beroe. The grazing impact of these communities must be substantial. QUANTIFYING THE PROPAGATION OF THE AMAZON RIVER PLUME IN THE WESTERN TROPICAL NORTH ATLANTIC

The Amazon River plume is significant in the biochemistry of the western tropical North Atlantic; it brings nutrients and organic matter to aquatic ecosystems and influences how ocean currents structure communities. As part of the ANACONDAS nitrogen fixation and carbon sequestration project, we investigate the physical aspects of the Amazon River plume that dictates its interactions with ocean waters. We combine data from a spring cruise with satellite data to estimate plume volume and age, demonstrating how remote sensing data can corroborate and enhance field measurements. With these data sources we further derive mathematical relationships relating plume surface salinity, CDOM, and the light attenuation coefficient at 490 nm. These relationships improve on previous estimates of salinity based on K90 and quantify the decay of CDOM with salinity and time. Our combined results offer a snapshot of the plume’s trajectory in the open ocean and further explain variations in biochemically relevant plume properties both spatially and temporally. A NEW CROSS-SHELF EXCHANGE MECHANISM: ON-SHELF ADVECTION OF SLOPE WATER WITHIN DISCRETE PYCNOCLINE TRAPPED LENSES

We present evidence of a shelf-edge exchange process, not previously identified, that is of importance for the transport of salt and biogeochemical properties onto the continental shelf. Lenses of high salinity slope water trapped within the pycnocline are observed 100 km or more from the Celtic Sea shelf-edge. The anomalies are typically 3-5 km in diameter and separated by 3-7 km, scales comparable to the internal Rossby radius, suggesting a geostrophically balanced feature optimum for maximum on-shelf dispersion. We propose that increased diapycnal mixing at the shelf-edge, associated with breaking internal wave packets, generated at a semi-diurnal frequency, is the mechanism by which high salinity slope water enters the pycnocline. These collapsing mixed patches are then advected on-shelf by residual flows of 0.02-0.06 m s⁻¹. An independent estimate of the advection speed, based on the expected rate of salt loss due to diffusion, compares favorably to observations and indicates timescale on the order of months. A combination of wind driven flow and transport by non-linear internal waves is thought to be responsible for this residual. (Abstract ID 9870)

INSIGHTS INTO IRON SPECULATION FROM THE IRON TRANSPORTERS IN MARINE BACTERIAL GENOMES

The drive to acquire any available form of iron, constrained by evolutionary pressure to keep only useful genes, suggests that the types of iron transporters in marine bacterial genomes should reflect the species of iron available in their niche. To gain insight into the most bioavailable forms of iron and the iron transport capabilities of marine bacteria, we searched marine bacterial genomes and metagenomes for a variety of iron transporters including Fe³⁺, Fe⁴⁺, siderophore, and heme transporters. In both the genomes and metagenomes Fe³⁺ ABC transporters were the most common iron transporters, consistent with the dominance of Fe(III), the thermodynamically stable state of iron, in the environment. Fe⁺ transporters were fairly common in both the genomes and metagenomes suggesting that Fe⁺ is relatively common in the environment and can be important source of Fe for some bacteria. Heme and siderophore transporters were frequently found in bacteria thought to be particle-associated, but not in exclusively free-living bacteria such as cyanobacteria and Pelagibacter ubique. This distribution of transporters indicates iron-siderophore and heme are present in the microenvironments that develop around organic particles, but are rare in bulk seawater. (Abstract ID 10847)

THE IMPACT OF WIDESPREAD SEDIMENTARY DENTRIFICATION ON THE BERING SEA SHELF

Continental shelf seas are hotspots for sedimentary denitrification, and as the largest contributor to global oceanic N loss, can have large implications in the global oceanic N budget. Through the Bering Sea Ecosystem Study (BEST) program, we measured the water column nitrate deficit and benthic fluxes of O₂ N₂, and inorganic nutrients on the Bering Sea shelf in the spring and summer from 2007 – 2010. Benthic O₂ consumption was largely similar among on-shelf stations, and ranged from 5 – 15 mmol O₂ m⁻² d⁻¹. Denitrification rates were similar over the entire shelf and at deep off-shelf sites and averaged 1.14 mmol N m⁻² d⁻¹. With widespread denitrification over the shelf, we estimate that N loss on the shelf and slope is at least 7.0 T N yr⁻¹. Sedimentary denitrification can account for the increase in water column nitrate deficit from summer to winter months. After the onset of water column stratification in the early summer, the nitrate deficit decreases only in the surface mixed layer; we propose that these results from high P requirements by blooming phytoplankton. CHANGES IN ATMOSPHERIC INTRASEASONAL FORCING AND EQUATORIAL OCEAN HEAT CONTENT IN THE RECENT DECADE

Variations in the warm water volume (WWV) of the equatorial Pacific and the atmospheric forcing from intraseasonal variation (ISV) in the western equatorial Pacific are regarded as two good predictors for subsequent ENSO with a lead time of two to three seasons. We use ocean and atmospheric reanalysis data to evaluate the relative importance of WWV variations and ISV forcing for the ENSO in the last decade. The characteristics of ENSO related to these predictors have changed in recent years. Previously the magnitude of ISV forcing in boreal spring was closely related to a subsequent ENSO between 1981-2000, but the analysis shows that ISV forcing in the last decade is uncorrelated with ENSO, especially for the El Niño/La Niña events after 2005. Additionally, the correlation between the WWV and subsequent ENSO has weakened in the last decade. These changes may be caused by a decadal change in the background tropical Pacific in which El Niño/La Niña evolves. (Abstract ID 10824)

MIXING AND INSTABILITY IN A RIVER PLUME FRONT

Mixing within river plume fronts is thought to contribute substantially to the overall mixing budget in the plume; however it is difficult to estimate because fronts are narrow and constantly moving. We use a combination of aerial infrared (IR) remote sensing and in-situ observations in the frame of reference of the Merrimack River plume front to examine the structure of the front and estimate the rate of mixing within it. The IR images are analyzed to generate surface velocity fields and we measured the vertical profile of salinity and temperature in the front. We construct a frontal control volume in the frame of reference of the front using the IR and density measurements to evaluate the relative importance of WWV variations and ISV forcing for subsequent ENSO with a lead time of two to three seasons. We use ocean and atmospheric reanalysis data to evaluate the relative importance of WWV variations and ISV forcing for the ENSO in the last decade. The characteristics of ENSO related to these predictors have changed in recent years. Previously the magnitude of ISV forcing in boreal spring was closely related to a subsequent ENSO between 1981-2000, but the analysis shows that ISV forcing in the last decade is uncorrelated with ENSO, especially for the El Niño/La Niña events after 2005. Additionally, the correlation between the WWV and subsequent ENSO has weakened in the last decade. These changes may be caused by a decadal change in the background tropical Pacific in which El Niño/La Niña evolves. (Abstract ID 10824)

THE PERFECT STORM SURGE: DETAILED DYNAMICAL CONDITIONS FOR
EXTREME SEA LEVELS

Globally, 200 million people live on coastal floodplains and about $1 trillion worth of assets lie within 1 metre of mean sea level. Increased flood frequency or severity would impact on economic and social systems. It is crucial to understand the drivers of extreme storm surges to have confidence in datasets used for extreme sea level statistics. We apply joint probability techniques to tide gauge data and find independence between the height of the tide and the skew surge (the time-independent difference between peak prediction and observations).

SYNTHETIC APERTURE RADAR WIND FIELD RETRIEVAL WITH RESPECT TO CYCLONES

Several synthetic aperture radar (SAR) images of tropical cyclones have been acquired by the C-band SAR aboard Envisat and Radarsat, as well as at the X-band SAR aboard TerraSAR-X and CosmoSkyMed, during the Office of Naval Research field experiment ‘Impact of Typhoon on the Ocean in the Pacific’ in summer of 2010. These SAR data provide a unique opportunity to investigate the utility of SAR data for estimation of extreme winds as well as other parameters useful for the improvement of tropical cyclone forecast. The resulting SAR-retrieved wind fields are compared to results of high-resolution numerical models as well as in situ measurements collected by aircrafts and buoy data. Uncertainty estimates are retrieved with respect to the low wind speed as well as wind imaging geometry. Furthermore, limitations of SAR wind retrieval at high wind speeds, in particular of the geophysical model functions (GMF) for retrieving wind speeds, will be addressed and discussed. Furthermore, assimilation of the SAR retrieved winds into the integrated tropical cyclone observing system H*WIND are presented. (Abstract ID 12181)

FIRST GENERATIONS OF INVASION: POPULATION STRUCTURE, COHORTS, IN SITU GROWTH RATES, AND PATCHINESS IN A BENTHIC BIVALVE COMMUNITY

Some of the most exciting ecology can be observed during the first few cohorts of newly establishing long-lived species. Bivalve mussels are suitable candidates because of their strictly benthic, though not sessile adult character; moderately long lifespan in the 5-10 year scale; prolific broadcast spawning form of reproduction; and absence of significant natural predators in deeper water. For Lake Michigan, invasion by Dreissena bugensis, the zebra mussel, was chronicled from first sightings through what we hope is the end of the first life cycle (2002-2011). Until 2005, divergent individual growth had not yet smeared cohort integrity, allowing estimation of actual in situ growth rates of 11-15mm/year from distinctly bimodal size-frequency distributions. Survival and recruitment of prey into the population was approximated using time series size-frequency analysis. Initial annual frequency and early fall timing of broadcast spawn settlement was apparent from sudden appearance of ~2mm individuals. Scarcity of empty shells indicated high recruitment after attainment of 4mm size, and longer life span that congenic zebra mussels. Patchiness was patchy, with large areas uniformly colonized at ~25,000 individuals/m² (maximum 40,206/m²). (Abstract ID 10900)

THE EFFECT OF STRATIFICATION ON WIND-DRIVEN, CROSS-SHELF CIRCULATION ON THE INNER SHELF

Three years of observations from the inner shelf south of Martha’s Vineyard, MA are used to describe the effect of stratification on wind-driven, cross-shelf circulation and transport. For along-shelf wind stress, the fraction of full Ekman transport scales with stratification, and the surface mixed layer thickness clearly limits the depth of the first zero-crossing of the velocity. For cross-shelf wind stress, stratification increases cross-shelf transport, but a 1D view of the dynamics is not sufficient to explain the relationship between circulation and stratification. For both wind orientations, the sign of wind stress driving offshore surface flow generates a more sheared circulation and a larger increase in transport between mixed and stratified conditions. SENSE IT: STUDENT-CREATED WATER QUALITY SENSORS

Sensor development is a topical and highly interdisciplinary field, providing motivating scenarios for teaching a multitude of science, technology, engineering and mathematics (STEM) subjects and skill sets. This presentation will describe the development and implementation of a carefully scaffolded set of high school curriculum modules, in which students build, calibrate and test a set of sensors and circuits, that integrate fundamental STEM principles while at the same time introducing students to the field of sensors and sensor networks—technologies that are increasingly important in all fields, but particularly in the world of environmental research. The project has been highly successful in a wide range of classrooms and the results of classroom implementation, during which 36 teachers were equipped, trained on curriculum, and implemented the modules with approximately 3,000 students will be presented. Results show that building and testing sensors engaged the students and increased their interest in STEM subjects and careers, and increased their understanding of fundamental concepts of electricity and increased their basic math (algebra) skills. Furthermore, their awareness of water quality as an environmental issue grew as well. (Abstract ID 9755)

UNDERWATER OPTICAL TURBULENCE AND IMPACTS ON BEAM SCINTILLATION

Underwater sensing is of primary importance to both civilian and military needs, in terms of visibility that are related to inspection needs, mine detection and identifications, search and rescues, and those applications linked to fundamental understanding of the oceanic processes. Optical turbulence has been known to degrade optical transmissions underwater. However, few studies have been conducted to understand and quantify the impacts until recently. Here we present recent lab and field efforts carried out by the US Naval Research Lab. Of these efforts, the focus will be on beam scintillation over transmission range, up to 5m, in lab tank, as well as from field exercises. Images obtained from a high speed camera are analyzed, along with optical and turbulence measurements. Optical properties of the water column are provided by ac-9 and LISST, while turbulence dissipation rates involving the temperature and kinetic energy are taken using Vertical Microstructure Profiler and 3D velocimeter Vector. The result of this study helps not only our understanding of the impacts on optical transmissions underwater, but also provides potential means to infer turbulence strength on a much more rapid time scale. THERMOHALINE VARIABILITY IN THE NORTHWESTERN MEDITERRANEAN BASIN OVER THE RECENT PERIOD (2007-2011) FROM IN-SITU MEASUREMENTS

Open-ocean deep convection is a key process that transfers the heat and salt contents from the surface to the deep ocean. In the Northwestern Mediterranean Sea, this leads to the formation of the Western Mediterranean Deep Water (WMDW) which underwent in 2005 an abrupt increase in its thermohaline properties, and an important modification in the deep stratification (known as the Western Mediterranean Transition, WMT). We present here new in-situ observations collected between 2007 and 2011 in the convection region to characterize the deep water formation variability and subsequent thermohaline changes. During this period, time series from a mooring describing the water column together with CTD, ARG0 floats and gliders profiles reveal three consecutive deep convection events that modified dramatically the deep water properties, including a salinity increase of 0.01 and a temperature increase of 0.03°C in 4 years. We attempt to assess the respective role of the interannual variability of the atmospheric forcings and of the water column stability on the intensity of the deep convection. (Abstract ID 9489)

A NOVEL METHOD TO QUANTIFY IN SITU GROSS PRIMARY PRODUCTION OF BENTHIC MICROALGAE USING TRIPLE OXYGEN ISOTOPE
We present a new method to quantify gross primary productivity (GPP) by benthic microalgae in an estuary, using the in situ triple isotopic composition of oxygen. Benthic microalgae significantly contribute to GPP; the total photosynthetic production, in many estuaries and coastal regions. Additionally, benthic microalgae are important in controlling fluxes of dissolved nitrogen between the sediment and water column. Therefore, production by benthic microalgae may be an important factor in the response of natural systems to eutrophication. We measure triple oxygen isotopic ratios (variations in ratios of $\delta^{18}O$, $\delta^{17}O$, and $\delta^{16}O$), successfully used for more than a decade in the pelagic ocean, in a novel experimental system to quantify in situ GPP by benthic microalgae in the Waquoit Bay estuary in Massachusetts, USA. The triple oxygen isotope technique relies on the fact that mass-independent fractionation in the stratosphere results in dissolved oxygen of atmospheric and photosynthetic origins having different isotopic compositions. Our approach will allow quantitative investigation of the response of benthic microalgal photosynthesis to eutrophication and vice versa. This approach may be globally applicable in estuarine and coastal environments. (Abstract ID 12759)

Gulf of Mexico Pilot Prediction Project (GOMEX-PPP): Model-Data Comparisons

Output from eight numerical circulation models simulating the Gulf of Mexico for 2010-2011 were compared with observations. Observed data included remotely-sensed SSH and SST fields, in situ point observations collected from moored and mobile platforms and data from submarine cables. We benefited greatly from existence of the Gulf of Mexico Coastal Ocean Observing System, an enhanced number of data sets resulting from the Deepwater Horizon incident and the Loop Current Study conducted by SAIC. Volume transport through the Yucatan Strait and Straits of Florida were computed and compared. Time series from vertical profiles of model currents were compared with full-water column profiles from ADCPs. Simulated Lagrangian particle trajectories were compared with drifter trajectories. Several approaches were taken to identify frontal locations in the Loop Current and Loop Current Eddies including objective automated machine estimates and subjective interactive graphical techniques. These were compared with frontal locations determinated by Horizon Marine Inc. surveys. A series of statistical metrics were computed to assess model skill. The goal is to identify the best model or models for an operational Gulf of Mexico modeling system. (Abstract ID 11793)

The Gulf of Mexico Coastal Ocean Observing System (GCOOS): A Data Stewardship Cooperative Supporting a Healthy Gulf

The Gulf of Mexico Coastal Ocean Observing System Regional Association (GCOOS-RA) is one of 11 regional observing systems that comprise the non-federal part of the U.S. Integrated Ocean Observing System (IOOS). GCOOS is composed of an increasing number of sub-regional observatories which make data available in near real-time through standardized interfaces. The GCOOS Data Portal assembles data from federal and non-federal partners and re-serves these in standardized and user-driven formats for human and machine consumption. Historical oceanographic data and operational numerical ocean circulation forecasts are housed and served. Common and specialized products are produced to serve the needs of various stakeholder groups. GCOOS-RA supports the Gulf of Mexico Alliance by participating in the activities of the Priority Issue Teams and the Gulf of Mexico Research Initiative. GCOOS is working with the GOMEX Pilot Prediction Project to select an operational circulation modeling system for the Gulf of Mexico and with the SURA modeling testing activity to develop a model infrastructure framework. These data stewardship activities are designed to increase knowledge to support decision-making leading to a sustainable healthy Gulf environment. (Abstract ID 11815)

Aloha Cabled Observatory: Early Results Including Acoustics

Since June 2011, the ALOHA Cabled Observatory (ACO) is providing power, network communications and timing to a seafloor node and instruments at 4728 m water depth 100 km north of Oahu. The ACO is a prototypical example of a deep observatory system that uses a retired first-generation fiber-optic telecommunications cable. The cabled observatory system will provide the infrastructure for continuous, interactive ocean sampling enabling new measurements and new modes of ocean observing that integrate ship and cabled observations. Present sensors measure currents, pressure, temperature, and salinity, along with video and acoustics. Turbulence, internal waves, tides and water mass mixing are evident. Prior acoustic data have provided new insights about surface ultra-gravity waves; continuing measurements and analysis will be shown, with examples of nearby earthquakes, distant T-phase arrivals, whales, ships and wind noise. To extend the spatial sampling footprint, the ACO will host water-column spanning profiling mooring systems and multipurpose active and passive acoustics systems, e.g., acoustic tomography. The Role of Salinity in North Atlantic Decadal Variability Simulated in a Coupled Climate Model

Several studies have shown that some features of observed decadal variability are simulated in a pre-industrial control run of the third Hadley Centre coupled climate model, HadCM3, such as Great Salinity Anomalies, (Wadley and Bigg, 2004) and anti-correlations between North Atlantic Oscillation indices and deep water formation (Cooper and Goedon, 2001). In this study we re-examine the role of salinity in decadal variability of deep convection in HadCM3. Surface salinity anomalies alter the surface density field as they propagate around the sub-polar gyre, resulting in decadal variations in the meridional and zonal surface density gradients across the southern limit of the gyre. These salinity-induced density gradients are highly correlated with Labrador and Greenland Sea deep convection and decadal variability in the pole–ward branch of Atlantic Meridional Overturning Circulation. The surface density anomalies also drive decadal variations in surface water mass transformation rates. We consider periods in HadCM3 which are comparable to the observational record and which are less than comparable, in order to explore how robust the relationships between salinity anomalies and the overturning circulation are in the model. New Exploratory Multibeam Data in the Drake Passage

The seafloor of the Drake Passage between South America and the Antarctic Peninsula has not been well mapped with multibeam sonar, largely because of its remote location and severe weather conditions. During two cruises of the RVIB Nathaniel B. Palmer in 2008 and 2011 we used the EM120 multibeam sonar system to map seven areas, ranging from the outer continental shelf and slope to the deep ocean basin, including two seamounts and part of the Shackleton Fracture Zone. The bathymetry provided a context for choosing sampling sites for paleoceanography studies as well as valuable insights on the regional geology. The multibeam maps, when compared to existing altimetry-derived bathymetric maps (Etopo1), show significant new detail at all sites. Volcanic structures and faulting related to seafloor spreading were mapped in detail, erosional features created by mass-wasting and/or high currents were discovered, and the depth of Sars Seamount was found to be lower than 100m. Allocating personnel for multibeam bathymetry data collection and processing during cruises of opportunity is a cost-effective way to further our understanding of seafloor geology, particularly in remote regions. Mesoscale Eddies in the Solomon Sea

High eddy activity in the interior Solomon Sea is a prominent feature of the sea level signal in the southwest Pacific. We investigate the mesoscale eddy field in the Solomon Sea using a 4-km resolution sigma-coordinate climate-forced (ROMS) model, nested in a basin solution, and evaluated against observational data. The model generates a vigorous upper layer eddy field. We diagnose the scales and vertical structure of the eddies in different parts of the Solomon Sea to illuminate their generation processes and propagation characteristics, and compare these to observed eddy statistics. Hypotheses tested are that the Solomon Sea mesoscale eddies are generated locally by baroclinic instability that the eddies are shed as the South Equatorial Current passes around and through the Solomon Island chain, that the eddies are turbulent features generated from instabilities of the swift western boundary current, or that eddies occurring outside of the Solomon Sea propagate or are advected into the Solomon Sea. These different mechanisms have different implications for the resulting mixing, and its timescales,
that may influence the properties of the equatorial undercurrent and subsequent cold tongue upwelling. They also provide different interpretations for SSH signals observed from satellites (e.g., that will be observed by the upcoming SWOT satellite). (Abstract ID 11449)

IMPACT OF THE GULF STREAM SST FRONT ON NORTH ATLANTIC CLIMATE VARIABILITY: A HIGH-RESOLUTION REGIONAL MODEL STUDY

The inability of the current generation of global climate models to realistically resolve the Gulf Stream separation from the east coast of the North America leads to improper representation of the associated sea surface temperature (SST) front in these models. To evaluate the impact of this misrepresented SST front on the overlying atmosphere, ensembles of high-resolution regional atmospheric model simulations are carried out, forced with SST simulated by an intermediate resolution and a high-resolution regional ocean model. It is found that the difference in the representation of the Gulf Stream separation between the two ocean model simulations has a significant impact on the climatologies of regional precipitation, stormtracks, and the remote large-scale mean background states. As the simulation of the Gulf Stream separation improves with the increase in the ocean model resolution, the associated shift in the SST front causes a northward shift of the winter storm track in upper levels as the synoptic disturbances propagate eastward. Moreover, a trough at low levels originates near the warm SST associated with the Gulf Stream separation and a strong anomalous ridge forms far downstream near the northeastern Atlantic and West Europe, which leads to a weaker subtropical jet near this region. These results support the notion of active frontal-scale air-sea interactions along the Gulf Stream and highlight the importance of resolving fine-scale structures in climate models. VERTICAL MIXING ASSOCIATED WITH NEAR-INERTIAL POINCARE WAVES IN LAKE MICHIGAN

In large lakes, near-inertial Poincare waves dominate the internal wave spectrum and are responsible for most of the vertical shear observed in the lake's interior during the stratified period. Our work seeks to test the hypothesis that basin-scale mixing in large lakes may be achievable in a fundamentally different manner than smaller lakes (and even ocean shelves), on account of the near-inertial character of the dominant internal seiche. We present thermocline shear and microstructure data from Lake Michigan in order to highlight the potential contribution of near-inertial Poincare waves to basin-scale mixing in the largest of lakes and enclosed basins. Of particular interest is the spatial and temporal distributions of vertical cross-thermocline shear, and the potential effects of these distributions on basin-scale cross-thermocline mixing. Episodes of particularly elevated shear are highlighted, and several existing shear-driven turbulence parameterizations are tested. Numerical model results are also presented in an attempt to generalize the conclusions beyond the measurement locations. (Abstract ID 10455)

HETEROTROPHIC RESPIRATION AND DENITRIFICATION OF SEDIMENTS IN THE LOW OXYGEN AREA OFF THE CHANGJIANG (YANGZIE RIVER) ESTUARY

Incubations of intact sediment cores revealed a positive correlation between oxygen consumption and denitrification in the mud region (r=0.68) of the Changjiang Estuary where the seasonal water column hypoxia has been reported. The average heterotrophic respiration rate measured as O$_2$ consumption was 357.2±206 μmol O$_2$/m$^2$/hour in the cruise in August 2011. The spatial pattern of respiration rates matches the areal distribution of mud. The hydrodynamic control on particles indirectly manipulates the sedimentary oxygen consumption. Denitrification outperforms Anammox in this area. The production rate of N$_2$O from denitrification was 9.7±7.8 and 2.2±3.2 μmol N/m$^2$/hour, respectively, which were determined by a newly developed isotope pairing technique. N$_2$O yields were lower than 10% of total denitrification in most of stations but higher than 70% at two stations with more aerobic surface caused by bioturbation. The intimate relationship among mud distribution, oxygen consumption and denitrification implies the effect of hydrodynamic driven substrate supply on sedimentary nitrogen removal processes. AN EXPERIMENTAL AND NUMERICAL INVESTIGATION ON WAVE-MUD INTERACTIONS

Wave attenuation over a fluid mud layer is investigated via laboratory experiments and numerical modeling in order to study wave-mud interaction and various mechanisms of energy dissipation. The experiments are carried out in a 2D wave flume in Tainan Hydraulic Laboratory, Taiwan. In all runs, the water depth is fix to be 30 cm with the bottom 6 cm cover by a mud layer made of fully saturated kaolinite. A fully developed fluid mud layer with a homogeneous concentration distribution is created to investigate the resulting energy
dissipation for different wave heights (2, 4, 6 and 8 cm), periods (0.6-2.1 sec) and mud densities (1200, 1310 and 1420 kg/m^3). Rheological analyses of mud samples suggest that in periodic motion the fluid mud displays very complex behavior. Empirical formulae are then developed to describe yield stress and viscosity as explicit functions of concentration and shear rate. Experimental results suggest non-linear wave effect reduces the viscosity and leads to less damping, and the Ilmenham plastic behavior of the mud layer also contributes to the development of boundary layer thickness. Measured data are used to validate a numerical model of wave-mud interaction based on RANS equations with a mixture formulation for mud transport. Empirical formulae developed from rheological analyses are implemented in the numerical model. The numerical model is then found to predict wave dissipation rate that agrees very well with the measured data. (Abstract ID 9472)
March, 2009 along a section crossing the shelf in the southern East China Sea to investigate the along-shore and cross-shore circulation and their response to wind. The observed residual currents over the shelf are strongly polarized in along-shore direction. The ZheMin Coastal Current flows from NE to SW in inner shelf and the Taiwan Warm Current (TWC) flows from SW to NE in mid-shelf. An Empirical Orthogonal Function analysis (EOF) is applied to residual currents. The first EOF mode explains 80% of the total variance with an in-phase spatial pattern of maximum amplitude at near surface 7km offshore. The first EOF temporal mode shows three peaks at 1.5d, 2-4d and 15d period. The residual currents are significantly correlated with local wind, and lags wind stress about 13h. The high correlation between the residual current and the wind stress suggests that the synoptic scale fluctuations of the coastal currents in the southern East China Sea are mainly forced by synoptic wind. SPATIAL AND INTER-ANNUAL VARIABILITY OF NCP AND GPP IN THE WESTERN ANTARCTIC PENINSULA REGION, 2008-2011

The distribution of net community production (NCP) and gross primary production (GPP) in the western shelf of the Antarctic Peninsula (WAP) has been studied during cruises in 4 consecutive Januarys (2008-2011). NCP and GPP are derived from measurements of [O

2

] ratios and the triple oxygen isotopic compositions of dissolved O2 in the mixed layer water. This study shows large spatial and inter-annual variability of NCP and GPP. In the shelf and coastal waters where there is no significant iron limitation, NCP and GPP are persistently negatively correlated with the mixed layer depth (MLD). These results suggest that light availability may be the key factor regulating NCP and GPP in the inshore WAP, and highlights the importance of various physical processes that strengthen upper water column stratification and relieve light limitation. Control of productivity by stratification is especially observed in the southern part of the study region for Jan. 2011, where low wind, high surface photosynthetically active radiation (PAR) and freshening of the surface water by ice melting acted together to facilitate anomalously high NCP and GPP. IMPACTS OF A WIND-DRIVEN, CROSS-SHELF LARGE RIVER PLUME ON BIOLOGICAL PRODUCTION AND CO2 UPTAKE IN THE GULF OF MEXICO

We used field surveys of partial pressure of carbon dioxide (PCO2) and satellite measurements of Chlorophyll-a data to examine how an unusual extension of the Mississippi and Atchafalaya River system (MARS) plume influences biological production and CO2 distribution in the northwestern Gulf of Mexico (GOM). An upwelling-favorable wind coinciding with a large freshwater discharge induced a wide-spread freshwater plume across the shelf in March 2010 with a pattern that is different from narrow plumes normally occurring in spring, such as Apr. 2009. This widespread cross-shelf MARS plume covered an area which is twice larger than the narrow plume area in Apr. 2009. In addition, this wide plume has nearly three times stronger CO2 uptake ability than the ability of plume in Apr. 2009, creating a CO2 sink for the atmosphere in a region that normally was a source of CO2, which significantly affected the air-sea CO2 flux of pelagic GOM. OBSERVED TYPE-A AND TYPE-B INTERNAL SOLITARY WAVES IN SOUTH CHINA SEA

A 143-day long mooring experiment was conducted in the deep basin of the South China Sea to observe internal solitary waves (ISWs). A total of 139 ISWs, including 51 type-a and 88 type-b ISWs, were recorded. The propagation directions of these ISWs showed that the middle and southern parts of the east ridge of the Luzon Strait were their sources. The generation areas of type-a and type-b ISWs was also overlapped and did not have an apparent boundary. In general, the arrival time of type-a and type-b ISWs followed the period of K1 and M2 tides, respectively. However, some unknown factors also affected the arrival time of most individual ISWs. Type-a ISW always changed into type-b ISW at the end of each type-a ISW group. In contrast, only three type-b changed into type-a ISW during June and July, 2010. Analyses of the changes between type-a and type-b ISWs around July 13 showed that the generation mechanism of ISWs could be very complex during such changes. (Abstract ID 10227)

CHEMICAL REACTIVITY AND SPECIATION OF DISSOLVED COPPER IN WEST PHILIPPINE SEA

Dissolved Cu in seawater is now recognized to be dominated by complexation with naturally occurring ligands. Marine humic substance (HS) are known to be one of the main components of bio-reactor DOM which plays an important role in copper speciation, affecting its bioavailability. In this study, depth profiles of the reactivity and speciation of dissolved copper in west Philippine Sea waters were investigated by cross flow ultrafiltration (1kDa), ion exchange (Chelex-100, APVIG 1), solid phase extraction (XAD-4, C-18) and differential elution (hydrochloric acid, sodium hydroxide and methanol) techniques. Results have shown that the concentration of dissolved Cu from surface to near bottom (3 m above sediment surface) waters ranged 0.5–5 nM. Chemical reactivity of dissolved Cu in the surface ocean had diurnal variations, which were mediated by colloidal compounds released from plankton and bacterial mineralization, as microbial mucilages. The fractions of dissolved humic bound Cu changed insignificantly through out the water columns, accounted for ~20–30 % of total dissolved copper. Less than ~2% of these reactive Cu were associated with low molecular weight fulvic acid, majority (>90%) were bounded with low molecular weight humic acids. (Abstract ID 10161)

MULTIDECADAL OSCILLATIONS OF THE MERIDIONAL OVERTURNING CIRCULATION IN PRESENCE OF BOTTOM TOPOGRAPHY AND STOCHASTIC ATMOSPHERIC FORCING

Flat-bottom idealized-geometry ocean models forced by fixed surface buoyancy fluxes show generic bifurcations towards multidiscal oscillations when the overturning circulation is large enough or the eddy-dissipation reduced. These oscillations are prevented in the presence of large-scale bottom topography like a Mid-Atlantic Ridge. Here we address this issue through a multimodel approach. We distinguish two main damping processes and quantify their relative influence: (1) the damping of Rossby basin modes through bottom-topography interactions; (2) the changes in the mean circulation with bottom topography that no longer supports unstable linear modes. On the contrary, stochastic NAO-like atmospheric forcing maintains these oscillations against bottom topography damping. The opposite influence of these processes on the multidiscal variability is investigated for actual North-Atlantic Ocean conditions. (Abstract ID 11002)

TOWARDS UNDERSTANDING THE DYNAMICS OF FRESHWATER AND SEDIMENT FLUX FROM THE GREENLAND ICE SHEET TO THE COAST WITH MODIS IMAGERY AND OCEANOGRAPHIC SURVEYS

Very few in-situ measurements of runoff from the Greenland Ice Sheet (GrIS) exist. We continue to develop the use of MODIS imagery to gauge river discharge of sediment and freshwater into fords hydrologically linked to the GrIS. To ground-truth satellite imagery and investigate the applicability of our methods to a range of Greenland’s ford-river systems we conducted oceanographic surveys of plume characteristics in five systems in Southwest Greenland. Orbital satellite calibration consisted of CTD, transmissometer, and in situ grain size analysis measurements. Ford conditions range from ocean to river dominated. Other plumes maintain low salinities (0 – 10 PSU) to depths exceeding six meters and down fjord over 65 km. Ford geometries, tidal range, and other conditions impact sediment plume dynamics. These dynamics must be accounted for to link plume imagery to discharge into the fords. Our insights into controls on plume processes help expand the method developed in a single end member fords to a wider spectrum of land-terminating outlets of the GrIS. (Abstract ID 12350)

FEEDING ECOLOGY AND CARBON TRANSPORT OF DIET VERTICALLY MIGRATING MYCTOPHIDS FROM THE NORTHERN MID-ATLANTIC RIDGE

Myctophids are among the most abundant vertically migrating fishes in the world's ocean, however little is known regarding their contribution to carbon export. We quantified diet depth distribution and analyzed the diet of myctophids from the northern Mid-Atlantic Ridge (MAR) between Iceland and the Azores in order to elucidate their role in the MAR food web and carbon export. The myctophid Boreogadus saida was the numerically dominant fish from the MAR, constituting 35% by number of the total fishes caught. This species was largely zooplanktivorous, with copepods and euphausiids comprising 59% and 15% of the diet by weight, respectively. By consuming zooplankton in surface waters and metabolizing their food at depth, myctophids may contribute to the biological pump, although, carbon actively transported to depth by migrating myctophids at the MAR varied along the ridge and was lower than export by vertically migrating zooplankton in the North Atlantic estimated in other studies. Due to their high abundance, myctophids not only directly contribute to carbon export, but also may exert top-down control on zooplankton communities, potentially affecting zooplankton-mediated carbon export. EDDY CORRELATION MEASUREMENTS WITH FAST OXYGEN OPTODES

Oxygen flux measurements in aquatic environments with the eddy correlation technique require fast sensors that can follow the rapid changes in flow and its oxygen concentration changes. We present measurements that demonstrate the suitability of fast optical oxygen sensors (optodes), in place of the traditionally used electrodes. Optodes have the advantage over microelectrodes of being less susceptible to signal drift, more durable under field conditions, less expensive, and repairable. Comparisons of the response times of optodes and electrodes to rapid oxygen changes showed that the optimized optodes had a slightly longer response time (169 ± 70 ms) than the microelectrodes (151 ± 60 ms) but were fast enough to capture the oxygen fluctuations that are relevant for the eddy correlation flux calculations. Side by side comparisons of benthic oxygen fluxes collected with both electrode-based and optode-based eddy correlation instruments in freshwater and marine environments showed good agreement between the measured fluxes. RANGE-WIDE, SEASONAL DISTRIBUTION OF GREEN STURGEON HABITAT IN THE PACIFIC OCEAN DERIVED FROM ACOUSTIC TAG DATA AND A REGIONAL OCEANOGRAPHIC MODELING SYSTEM

The anadromous green sturgeon (Acipenser medirostris) is found in the eastern Pacific from Baja California to the Bering Sea. Previous studies show sturgeon to be highly migratory throughout this range, moving long distances among estuaries, spawning rivers, and distant regions of the coastal ocean. Factors determining the distribution of green sturgeon within this region are unclear; but broad scale ocean conditions may be important. We report the results of an acoustic tagging study that used data-logging hydrophones from the Pacific Ocean Shelf Tracking experiment. We connected modeled bottom temperature, dissolved oxygen, geostrophic currents, and depth to acoustic detections using a maximum entropy model. We then described the seasonal distribution of marine habitat and its overlap with bottom-trawl fishing. We found that sturgeon migrated seasonally with the prevailing currents and that depth, dissolved oxygen, eddy kinetic energy and temperature were important determinants. Our study is the first to utilize output from a regional oceanographic model to delineate sturgeon habitat and will provide insight concerning the effects of changing ocean conditions and fisheries management. MIXING EFFICIENCIES OF OCEAN PROCESSES: INSIGHTS FOR THE ENERGY BUDGET OF THE GLOBAL CIRCULATION

The amount of energy required to support turbulent mixing represents a major unknown in the global oceans. We discuss the insight offered by recent laboratory measurements of the efficiency of several mixing processes. The results suggest that shear instabilities in exchange flows and overflows rise to substantially less mixing than would be estimated from the commonly assumed efficiency of 20%. Conversely, recent measurements suggest that mixing associated with the large scale convective overturning can be characterized by much higher efficiencies. These findings prompt new questions regarding the energy requirements of the global circulation. (Abstract ID 9921)

INFLUENCE OF SST ON SURFACE WINDS: BAROCLINIC VS. STABILITY IMPACTS

The effects of baroclinicity and stability on oceanic surface winds in the presence of an idealized sea surface temperature (SST) front are investigated using the University of Washington planetary boundary layer (UW-PBL) model. On spatial scales of O(1000 km), a definitive relationship between SST and surface winds (and wind stress) is observed in regions of strong SST fronts, where winds are generally higher (lower) over relatively warm (cold) water. Debate remains as to the physical mechanisms responsible for the small-scale coupling between SST perturbations and surface wind. O'Neill (2011), using in situ observations, concluded that the surface layer stability does not appear to strongly influence the surface wind stress response to small-scale SST variability. This study demonstrates that under certain conditions either the baroclinic or stability effects can dominate. (Abstract ID 11868)

RADIONUCLIDE INDICATORS OF SEASONAL SEDIMENT DEPOSITION IN THE DELAWARE ESTUARY

A study was conducted to determine how fine sediment deposition in the turbidity maximum zone of the Delaware Estuary varies with seasonal river discharge conditions. Beginning in spring 2011, coring stations were reoccupied seasonally to measure activity profiles of 1-131 (8.0 day half life), Be-7 (53.3 day half life), and Pb-210 (22.3 year half life), which is derived from wastewater effluent discharged at head of the estuary, provided information on sediment transport distances, whereas cosmogenic Be-7 was used along with excess Pb-210 to determine the relative age of bed deposits. During a period of low river discharge in summer, new deposition was centralized in the upper estuary near the salt intrusion. In September, following extreme river discharges associated with Hurricane Irene and Tropical Storm Lee, the upper estuary floor was scoured and the mud depocenter migrated seaward along with the salt intrusion. The new deposits were enriched in Be-7 and I-131, demonstrating that fine sediment resident in the tidal freshwater segment was swept seaward to the middle estuary within just days of the storm-produced riverflow events. SUMMER PARTICULATE ORGANIC CARBON FLUX IN THE EAST CHINA SEA

Recent studies have shown that continental marginal sea is wealth of nutrient which can promote the growth of phytoplankton and the absorption of atmospheric CO2. These carbon source fixed by phytoplankton were possibly transported to the open ocean by the continental shelf pump mechanism. The previous studies have shown the vertical particulate organic carbon (POC) flux in the East China Sea (ECS) are usually higher in the in-situ primary production. Therefore, this study was performed to measure the POC in the ECS with floating sediment trap and the re-suspension was confirmed with two-component mixture model. The result was showed that uncorrected POC flux in the inner shelf was 720-8790 mgC/m2/d and was gradually decreased to 80-150 mgC/m2/d in the outer shelf. Although there was not any effect on the distribution of POC flux after correction, but the POC flux values, 49-3499 mgC/m2/d were apparently lower than uncorrected values. The result was showed that 24-98% POC flux was generated by re-suspension of the particles at the bottom rather than the biological particles from the ocean surface. The flux of vertical, buried and remineralized POC at the edge of shelf was 49-50, 5-9 and 6 mgC/m2/d, respectively. It is estimated that about 33-39 mgC/
m2/d biological POC was exported to the ECS. (Abstract ID 9591)

DIVERSITY AND ACTIVITY OF BACTERIOPLANKTON IN THE NORTH PACIFIC (STATION ALOHA)

Culture independent studies have revealed marine bacterioplankton to be exceptionally dynamic and genetically diverse, yet how the activity of these microbes varies between clades or with time and space is largely unknown. Here using paired large-scale pyrosequencing of ribosomal DNA gene (rDNA) and ribosomal RNA (rRNA) libraries, we investigate the relative activity of microbial communities from two depths (25 m and 100 m) at a representative site in the north Pacific Ocean (Station ALOHA). Sequences from a 454 library with >500,000 reads were trimmed, denoised and chimeras checked using QIME. Sequence clustering at 97% identity identified ~1,400 operational taxonomic units (OTUs). Prochlorococcus and SAR11-like sequence types dominate the libraries at both depths. Comparisons of sequence abundance between the libraries revealed patterns with depth and apparent uncoupling of abundance (rDNA) and activity (rRNA). These data provide insight into the activity of specific members of the microbial community, and more broadly applied this technique may help to distinguish the roles of specific clades within diverse marine bacterioplankton communities. LAGRANGIAN OBSERVATIONS IN THE JAMES RIVER ESTUARY - 2010 DYE INJECTIONS, LATERAL MIXING AND THE SPING-NEAP CYCLE.

During May of 2010, a series of four dye injections was carried out over a spring-neap cycle with the objective of quantifying diurnal mixing and lateral circulation in the James River Estuary. Fluorescein dye was injected into the bottom boundary layer near Newport News, VA, on May 5th, 7th, 25th and 27th. The survey plan which mapped each dye patch consisted of two vessels, one equipped with a CTD profiler to map the along-channel extent and variability of the dye patch, the other with a towed undulating CTD cage for cross-channel transects. In addition, a high resolution moored instrument array was deployed for the duration of the survey. Data from the dye surveys and mooring array is presented here. The four dye injections consisted of flood and ebb injections during a spring and neap tide. The dye surveys yielded from 6-8 synoptic realizations of the dye patch for each injection. Analysis will access if a simple 1-D mixing model can explain the observed salting of the dye patch based on estimates of shear production from both moorings and microstructure data. NEW ALGORITHM FOR REMOTE SENSING OF VARIABILITY IN THE QUANTUM YIELD OF CHLOROPHYLL FLUORESCENCE

The emission of fluorescence from chlorophyll within phytoplankton cells illuminated by sunlight (i.e. sun-induced chlorophyll fluorescence [SIF]) varies due to four main variables: the quantum yield, the incident irradiance, the absorption coefficient of phytoplankton, and the total absorption coefficient of the water. Consequently, remotely measured SIF should contain information on all four variables. Here we examine how standard ocean color algorithms can benefit from utilizing Sun-induced fluorescence to improve our accuracy. We follow this analysis by presenting a new type of algorithm to observe variability in the quantum yield of fluorescence. We show that this algorithm provides fields that are vastly different from previously derived algorithms at the global scale. (Abstract ID 12079)

DIFFERENTIAL SUSCEPTIBILITY OF COASTAL CALCIFIERS TO OCEAN ACIDIFICATION

Trends in pH at the surface of three ecologically important cold-water calcifiers (coralline seaweed, abalone, urchin), under a range of fluid flows, differ substantially from one another and, for two of the three calcifiers, the pH in darkness is lower than that projected for the surface waters beyond the year 2100. Using micro-probes, we show that abalone encountered only mainstream seawater pH4, whereas pH at the sea urchins’ surface was reduced by ~0.35 units. For coralline algae, pH4 was ~0.5 units higher in the light and ~0.35 units lower under darkness than in ambient mainstream seawater. This wide range of pH within the diffusion boundary layer of some calcifiers could affect their performance under projected future reductions in pH due to OA. Differing exposure to a range of surface pH may result in differential susceptibility of calcifiers to OA. Our study, by considering physics (flow regime), chemistry (pH gradients vs. OA future projections) and biology (trophic level, physiology and morphology), reveals that predicting species-specific responses and subsequent ecosystem restructuring to OA is complex and requires a holistic, eco-mechanical approach. THE ROLE OF SEA ICE DYNAMICS IN INCREASING LATITUDINAL EXPANSION OF THE SEASONAL ICE ZONE IN THE CHUKCHI AND BEAUFORT SEAS.

The Chukchi and Beaufort Seas have lost perennival ice cover since 1997. After the record Arctic sea ice minima of 2007, the Beaufort seasonal ice zone continued to expand. The Chukchi and Beaufort ice packs are closely coupled through Beaufort Gyre return of ice from the Chukchi to the Beaufort, and export of multi-year ice from the Beaufort to the Chukchi. We show that since 1997 import of multi-year ice to the Chukchi has been hindered by increasing summer melt in the Beaufort. Recirculation in the Beaufort Gyre comprises first year ice from the Chukchi, that has acted to create an ice pack younger than 5 years old throughout most of the extent of the Beaufort Gyre. This relatively young Beaufort ice (compared to conditions prior to 1997) melts out completely below 76N. Older ice is exported from the Canadian Holding zone into the Southern Beaufort, where ship observations from the CCGS Louis S. Laurent demonstrate a diffuse ice pack that has experienced substantial melt in summers 2007-2011. Hence the survivability of the oldest ice traversing the southern Beaufort Sea is reducing. To increase perennial ice area in the Arctic requires consolidated ice older than 10 years drifting in the southern Beaufort (like 2006), followed by recirculation of this in the Beaufort Gyre (unlike 2006, where this ice was exported to the transpolar drift). CAN CHANGING PCO2 CONTROL THE GLOBAL DOMINANCE AND DIVERSITY OF N2-FIXING CYANOBACTERIA?

Studies showing N2 fixation rate increases with rising pCO2 in marine diazotrophic cyanobacteria have all used the same one or two culture isolates, raising questions about relevance to large-scale environmental trends. We generated CO2 response curves (0-2000 ppm) for N2 fixation rates using seven Pacific and Atlantic Trichodesmium and Crocosphaera isolates from a global culture collection. Responses to changing pCO2 were variable and strain-specific, with N2 fixation half saturation constants (K1/2) ranging from 63-408 ppm CO2. Using these K1/2 values and GMC simulated changes in sea surface pCO2 we estimate the potential N2 fixation rates of each isolate from last glacial maximum (LGM) to projected year 2100 concentrations. As pCO2 levels rise from the LGM to today and over the next century, strain-specific differences in the magnitude of maximum N2 fixation rate responses to CO2 fertilization are on the order of 200-300%. CO2 availability could therefore be a powerful selective force determining the relative competitive success of different Trichodesmium and Crocosphaera species and ecotypes, and so may help to shape the global distributions and biodiversity of marine N2-fixing cyanobacteria. METABOLIC CONSEQUENCES OF SURFACE RUNOFF AND GROUNDWATER INPUT TO A COASTAL MICROBIAL COMMUNITY: CONTRASTING EFFECTS OF TERRESTRIAL LANDSCAPES AND FLOW

Frequent hypoxic events in Long Bay, South Carolina occur despite a lack of substantial riverine or upwelled inputs. One theory suggests that nutrient-rich groundwater is being contained nearshore via limited cross-shelf mixing others suggest that stormwater run-off channelized through small tidal creeks or outfall pipes is delivering nutrients and organic matter that initiate conditions that subsequently lead to hypoxia. In an effort to understand
the effects of input source on key biological rate processes, surface water and groundwater from developed (Myrtle Beach) and undeveloped (North Inlet) uplands was introduced to a coastal water microbial community in a controlled microcosm experiment. Both treatments from the developed basin resulted in a more heterotrophic system than the control while both treatments from the undeveloped basin resulted in greater autotrophy. Surface run-off additions operated higher levels of production and a much more heterotrophic system than all other treatments, likely because impervious surfaces in the developed basin re-route a significant proportion of allochthonous nutrients through surface, rather than subsurface flowpaths compared to the undeveloped basin. MICROBIALITES AS POSSIBLE FRAMEWORK CONTRIBUTORS FOR MESOPHTHIC CORAL ECOSYSTEMS (MCES)  
Microbialites are defined as lithified cemented deposits formed by benthic microbial fauna. In reef environments, microbialite communities often correspond to episodes of elevated nutrient levels and sea surface temperatures. However, current observations of microbialite structures in modern substrates from mesophotic coral ecosystems (MCES), far from anthropogenic and terrestrial influences, indicate recent formation under oligotrophic conditions. Substrate hand samples collected from MCES off La Parguera, Puerto Rico, suggest that microbialites can contribute to the reef framework, by encrusting and stabilizing loose sediments, possibly creating new habitat suitable for coral recruitment and colonization, which is known to be limited in these ecosystems. Although coral-microbialite dynamics are not well understood, documenting microbialite morphology and development, as well as environmental conditions that promote their growth will contribute to understanding their function in mesophotic reef communities. The present study is based on the identification of possible microbialites within MCESs and provides data of growth patterns and contributions to framework building. (Abstract ID 10794)

ALKENONE UNSATURATION AND FLUXES ON THE NORTHWEST ATLANTIC MARGIN  
Alkenone unsaturation index (UK\textsuperscript{37}) has been used widely in paleotemperature reconstruction. It is important to understand how faithfully marine organisms record the growth temperature and this temperature signal is transferred to the sediment. Tied sediment trap arrays can provide useful information on the biogeochemical processes that partition organic matter (POM) undergoes during passage through the water column and on the transfer and preservation of signals of surface ocean. We examined alkenone distribution in sinking POM intercepted at three nominal depths-1000m, 2000m, and 3000m (50m above the bottom)- on the North Atlantic margin from 2004 to 2007. UK\textsuperscript{37} did not exhibit any significant trend with increasing depth, supporting the previous observations that UK\textsuperscript{37} is not altered despite several-fold attenuation in alkenone flux. Alkenone flux decreased from 1000m to 3000m as a linear function of the alkenone flux at 1000m with a positive slope, indicating talinum was not altered despite several-fold attenuation in alkenone flux. Alkenone flux decreased from 1000m to 3000m as a linear function of the alkenone flux at 1000m with a positive slope, indicating

WHEN AND WHY ARE ZOOPLANKTON PIGMENTED?  
The reddish color of salmon flesh is caused by pigments called carotenoids. These substances are common in nature and have many beneficial functions. Accumulated carotenoids can for example function as "suntan" for zooplankton (copepods) reducing ultraviolet radiation (UVR) damages on DNA, but pigments also increase the animals’ visibility to predators. Other UV-protective compounds such as mycosporine-like amino acids (MAAs) provide sunscreens but are non-pigmented. They are hence hypothesized to give UV-protection without increasing the predation risk. Our results from laboratory and field studies show that accumulation of carotenoids and MAAs is dependent on food source and level of UVR exposure. Egg production and growth rates are negatively affected by UVR but this negative effect is reduced if MAA-rich algae are included in the food. This indicates that zooplankton can detect changes in UVR and optimize their blend of UV-defensive compounds. The preference of non-pigmented MAAs over red carotenoids may be an adaptation to high predation pressures in pelagic habitats in the ocean. (Abstract ID 11951)

A DAY IN THE LIFE OF A PHYTOPLANKTER: AN INDIVIDUAL-BASED MODEL OF DIET CYCLING IN PROCHLOROCOCUS Prochlorococcus spp. are the smallest and most numerous phytoplankton in the ocean, producing about 1/5 of the oxygen we breathe. The tightly-phased diel dynamics of growth and division can be used to estimate growth and mortality rates of Prochlorococcus both in situ and in silico. In this study, we used an individual-based model (IBM) to capture the cell size patterns, cell concentrations, and cell cycle phase distributions of Prochlorococcus in order to elucidate factors driving cellular dynamics. The model was compared to cell cycle data from field populations in the Sargasso Sea of the North Atlantic Ocean. We have found that there is a threshold cell size for the initiation of DNA replication, we must sufficiently reproduce the dynamics of cell size in order to accurately model in situ Prochlorococcus cell cycle dynamics. This model has been used to test the effects of sampling frequency on field calculations of growth rate from cell cycle parameters (Carpenter & Chang, 1988). In future studies, the model can be embedded in a 3-D circulation model to investigate the effects of light, nutrients, and grazing on Prochlorococcus population dynamics. (Abstract ID 10481)

ANALYZING SATELLITE DERIVED PHYTOPLANKTON FUNCTIONAL GROUP ESTIMATES FOR USE IN FISHERY PRODUCTION MODELS  
Fishery production potential is a function of primary production, the fraction of production available to higher trophic levels and trophic transfer efficiency. Two pathways are recognized for trophic transfer of primary production in marine ecosystems – direct grazing by mesozooplankton, principally on diatoms; and nanoplanクトon production transferred through the microbial food web with a greater number of trophic transfer steps. Analyses in northeast U.S. continental shelf Large Marine Ecosystem (LME) suggest that phytoplankton biomass has increased up to 33% during the last decade compared to the 1970-80s. However, phytoplankton composition data from the Continuous Plankton Recorder (CPR) shows a decrease in large diatoms and dinoflagellates species abundance. The goal of this current study is to evaluate the speciess in phytoplankton species composition using various remote sensing phytoplankton functional group size class models and then incorporate this data into estimates of size fractionated primary production. A possible shift from larger to smaller phytoplankton species has important fisheries implications because it can impact the total amount of production in the system available to higher trophic levels and affect the fishery production potential. COASTAL UPWELLING AND LAND HEATING OVER THE CALIFORNIA-OREGON COAST: DYNAMICS AND CLIMATE SCALE LAND-OCEAN-ATMOSPHERE INTERACTIONS

Long-term buoy observations suggest that the summertime water temperatures off the US West Coast have been steadily declining since the 1980s, with the greater cooling trends in central-southern California compared to Oregon-northern California. While alongshore wind stress exhibits the opposite trend patterns, the wind stress curls in the south have become increasingly cyclonic, implying a possible role of topographically-driven wind stress curls in the upwelling trend pattern. With cooler coastal waters, the daytime near-coast land air-temperatures have been declining due to stronger sea breezes, in contrast to the continuous inland warming. A popular hypothesis posits that strengthened upwelling and sea breezes are associated with the anthropogenic greenhouse gas forcing. Analyzed upwelling fields, however, also exhibit large interannual to multi-decadal variabilities coherent with major modes of climate variability. To attribute the observed variability and trends objectively to these remote, local and anthropogenic causes, process modeling studies will be reported using a high-resolution regional air-sea coupled model over the US West Coast. This is a critical step toward the robust projection of potential coastal climate responses to various climate change scenarios. (Abstract ID 10030)

PALEOCENOGRAPHIC ENVIRONMENTAL EVOLUTION IN THE EAST SEA (JAPAN SEA) SINCE THE LAST 400 KYR

Geochemical proxies of stable oxygen isotope of foraminifera, carbon and nitrogen isotope of organic matter, and total organic carbon (TOC) and inorganic carbonate content of two piston cores taken from the Korea Plateau, East Sea (Japan Sea) were investigated to understand the paleoenvironmental evolution since the last 400 kyr. Oxygen isotope signals of foraminifera shows large fluctuation, ranging from MIS (Marine Isotope Stage) 1 to MIS 11. Comparison of oxygen isotope record during the 400 kyr reveals that paleoceanographic and paleoclimatic changes in the East Sea is quite different from those of open oceans. The content of biogenic carbonate, TOC and carbon and nitrogen isotope of organic matter (δ13C and δ15N) were determined and used to interpret paleoenvironmental changes during glacial and interglacial periods. Based on the isotopic composition of δ13C and δ15N, which showed extreme temporal variation since MIS 11 influx of large amount of terrestrial organic matters from the neighboring continent during MIS 2, 8 and 10 can be implied. In particular, depleted values of δ13C during MIS 2, 8 and 10 were coincident with lower nitrogen isotope values indicating local paleoceanographic effects such as paleo productivity changes. Therefore, the paleoenvironment in the East Sea is sensitive to the global climate changes associated with not only orbital-scale glacial-interglacial variations but also local paleoclimatic variations. IMPACT OF NON-VOLATILE DIATOM OXIDINES ON THE REPRODUCTIVE SUCCESS OF THE COEPOD TEMORA STYLIFERA

Abstract: Diatoms produce toxic compounds that inhibit growth and reproduction in copepods. The toxic effects of some oxidenones is well known, for example those of polyunsaturated aldehydes (PUAs), while questions remain on the toxic nature of others. We compared the effect of PUAs found in Skeletonema marinoi to the effect of hydroxy fatty acids (HEPA) found in both S. marinoi and Pseudoschizochytrium delicatissimum which does not produce PUAs. Using an experimental approach we measured reproductive parameters in the copepod Temora stylifera for 15 days. Egg production, egg viability and naupliar recruitment were negatively affected with both diatoms. Hatched naupli were often abnormal and positive to apoptosis. The most common hydroxycyclo (15S-HEPA) tested on newly spawned eggs, reduced hatching success and induced apoptosis, at higher concentrations compared to PUAs. Other hydroxycyclids (5-9 and 11-5 HEPA), which vary only in the position of the hydroxy group, were more active. Thus diatoms produce a variety of compounds that negatively affect the growth and reproduction of copepods. (Abstract ID 12576)

PARTICLE KALMAN FILTERING: A NON-GAUSSIAN BAYESIAN FRAMEWORK FOR ENSEMBLE KALMAN FILTERS

This contribution investigates an approximation scheme of the optimal nonlinear Bayesian filter based on the Gaussian mixture representation of the state probability distribution function. The resulting filter is similar to the particle filter, but is different from it in that, the standard weight-type correction in the particle filter is complemented by the Kalman-type correction with the associated covariance matrices in the Gaussian mixture. We show that this filter is an algorithm in between the Kalman filter and the particle filter, and therefore is referred to as the particle Kalman filter (PEKF). In the PEKF, the solution of a nonlinear filtering problem is expressed as the weighted average of an ensemble of Kalman filters" operating in parallel. Running an ensemble of Kalman filters is, however, computationally prohibitive for realistic atmospheric and oceanic data assimilation problems. For this reason, we consider the construction of the PKF through an ensemble of ensemble Kalman filters (EnKFs) instead, and call the implementation the particle EnKF (PEnKF). We show that different types of the EnKFs can be considered as special cases of the PEnKF. Similar to the situation in the particle filter, we also introduce a re-sampling step to the PEnKF in order to reduce the risk of weights collapse and improve the performance of the filter. Numerical experiments with the strongly nonlinear Lorenz-$96$ model are presented and discussed. (Abstract ID 9375)

IMPACT OF A FINE SCALE SST OVER THE KUROSHIO EXTENSION REGION TO WINTERTIME RAINFALL

In the present study, the winter precipitation in the vicinity of Japan is simulated by the Weather Research Forecasting model by using two sets of sea surface temperatures (SSTs) data with different spatial resolutions. It is found that the difference in the SSTs resolution has the interannual variance of the local precipitation over the Kuroshio–Oyashio Extension (KEO) region. The warm (cold) SST anomaly in the KEO region near Japan, caused by ocean processes, induces an increase (decrease) in the local precipitation to the east of the SST anomaly. This increase is accompanied by the enhancement of surface wind convergence (divergence). Furthermore, the anomalous ascent associated with the enhanced surface wind convergence in response to the warm SST anomalies extend to the mid-troposphere up to around 500 hPa, this is accompanied by an increase in the cloud ice. This suggests that the SST in the KEO region can affect the atmosphere above the planetary boundary layer. Moisture budget analysis indicates the influence of moisture advection by mean wind on the spatial phase difference between the SST and precipitation anomalies. (Abstract ID 9835)

ATTEMPT OF MODEL INTER-COMPARISON PROJECT FOR RADIONUCLIDE DISTRIBUTIONS FROM FUKUSHIMA-I

Radionuclide-polluted water flowed out of Fukushima-I in early April, Radionucleotides also fall out from the atmosphere in March and spread much more widely than the water flow. The ocean simulation models were developed to reproduce current patterns and radionuclide distributions, under atmospheric forcing and river flows. For the coastal region, the models were applied to reproduce freshwater- and wind-driven coastal currents and nested with the offshore mesoscale features, which were updated with data assimilation. A systematic inter-comparison of these models (MIP) was useful for higher reliability of the simulations. The models were first verified against current meter data before the event. With the two kinds of radionucleotides, the polluted water spread along the coast southward on the average with variations due to winds and was gradually taken away within the mesoscale eddies. In addition, low-level pollution spread along the Kuroshio Extension and also the general circulation for a few years. Even though the current patterns were reproduced consistently among the models, the radionuclide contents showed significant differences in the southern coastal region. The component in sediments was also estimated. (Abstract ID 9340)

A COMPARISON OF NEARSHORE KELP HABITATS ACROSS THE ALASKAN ARCTIC COAST

Rocky habitat dominated by kelps is rare in the nearshore Arctic, but where they occur, these habitats are known to be distinct biodiversity hotspots. These boulder regions are ecologically important because they support benthic primary producers with tightly linked food webs. Here we present the first results on the exploration of a new boulder field in the coastal Chukchi Sea

TOS/AGU/ASLO 2012 Ocean Sciences Meeting

2012 Ocean Sciences Meeting

8/13/2012

210
near Barrow, including a first quantitative biological description of this boulder community. We also compare this community to other such kelp communities in the coastal Beaufort Sea. Our results show that these nearshore boulder communities along the Alaskan Arctic shore share many of their community elements but that each community also has dominant members that are inefrequent at the other locations. This indicates that dispersal and exchange among these communities may be limited and a substantial amount of local recruitment may occur. (Abstract ID 9400)

SPURIOUS DIAPYCNAL MIXING AND THE ROLE OF MOMENTUM CLOSURE

Spurious numerical mixing needs to be minimized in order to investigate the global sensitivity to spatial distribution of mixing. One of the main motivations to understand and reduce spurious dianeutral transport is due to the need to retain water masses over basin scales for timescales of decades to centuries. Explicit mixing values can be masked by the implicit numerical mixing in geopotential and sigma coordinate ocean models. Performance of four different ocean models (GOLD, MITgcm, MOM and ROMS) has been investigated using four different idealized test cases (lock-exchange, overflow on a slope, internal waves and eddying channel). Simulations with the isopycnal model GOLD provide a benchmark for the smallest level of spurious mixing. ROMS generally produces smaller spurious dianeutral mixing than MITgcm or MOM, since ROMS employs a higher order upwind-biased scheme with less mesoscale eddies. The GOLD simulations have detectable levels of spurious cabbeling from simulations with the isopycnal advective truncation errors. Significantly larger spurious mixing arises in a non-eddying MOM simulation. In an eddying MOM simulation, spurious dianeutral transport is larger still but is reduced by increasing momentum friction. (Abstract ID 10817)

TURBULENT MIXING AND HEAT DELIVERY IN A SE GREENLAND FJORD: THE ROLE OF PSW.

The region of greatest mass loss from the Greenland Ice Sheet is the southeast, where icebergs calving from marine-terminating outlet glaciers dominates mass loss. The main outlet glaciers terminate at the heads of deep, long fjords which extend as troughs as far as the shelf break. Accelerated ice loss has been attributed to changing oceanic conditions, both in deeper Atlantic-origin waters, and in shallower Arctic-origin waters (Polar Surface Waters, PSW), although evidence for this is sparse. Concentrating on Kangerdlugssuaq Fjord, this presentation quantifies the role of fjordic circulation in transporting oceanic heat along the axis of the fjord. Historic and recent (2010) hydrographic and velocity measurements are used to diagnose a circulation scheme. Full-depth turbulence microstructure measurements, which reveal highly turbulent upper layers atop more intermittently turbulent deeper layers, are combined with the circulation scheme to construct layer-wise heat and salt budgets. PWS emerges as a key player in the melt-rate equivalent residual of the heat budget. Results of 3D hydrodynamic modelling demonstrate a circulation pattern consistent to that diagnosed from the observations. (Abstract ID 11194)

GLOBAL BAROTROPIC OCEAN MODELING DRIVEN BY SYNTHETIC ATMOSPHERIC DISTURBANCES: VALIDATION USING GLOBAL IN-SITU OCEAN BOTTOM PRESSURE DATA

A global barotropic ocean model forced by atmospheric disturbances is developed and validated by global in-situ ocean-bottom pressure (OBP) data. Parameters and boundary conditions of the model are tested in order to accurately simulate non-tidal (<2 days) OBP variations. The horizontal resolution of the model most strongly affects the model output. The finer the horizontal resolution is applied, the weaker the model variabilities are. The model accuracy is highest when the horizontal resolution is 1/12 deg. At a period of 2-20 days, the 1/12 deg. model yields a correlation coefficient of 0.66 to the OBP observations on global average. The 1/12 deg. model is shown to be useful to reasonably detect slow vertical seafloor deformation of centimeters in timescales of days from in-situ OBP records. On the other hands, high resolution models with grid sizes of finer than 1/12 deg. yield worse results, which is discussed. (Abstract ID 10999)

SUSTAINED CABLED OCEAN OBSERVING SYSTEMS FOR MANAGING FISHERIES WEALTH IN THE SEA OF OMAN AND ARABIAN SEA

In 2005 Lighthouse R&D Enterprises, Inc. began developing an ocean observing system that would help manage fisheries wealth for the Sultanate of Oman. The resulting cutting-edge, fiber-optic cabled observatory was installed in the northern Sea of Oman and became operational in August, 2005; this summer the system surpassed the milestone of 2100 days of successful operation. A second, deepwater cabled observatory was installed where the Sea of Oman meets the Arabian Sea, in January, 2010. Both systems monitor physical properties throughout the water column including current velocity, temperature, pressure, conductivity, dissolved oxygen and turbidity. The entirely subsea nature of the fiber-optic cabled observatory capitalizes on several advantages over traditional buoyed systems including lack of exposure to environmental wear and tear, collision, vandalism and theft. The systems are cabled to nearby shore facilities, where data are relayed instantly to Houston via satellite for processing, analysis and modeling – the data may also be used in making real time decisions. The design and obstacles, lessons learned and scientific questions being addressed by the Lighthouse systems will be covered in this presentation. (Abstract ID 12820)

INTERNAL WAVES, SHEAR INSTABILITY, AND TURBULENCE BELOW THE SURFACE MIXED LAYER OF EQUATORIAL PACIFIC.

The entrainment heat flux below the surface mixed layer is important to the heat budget of the Pacific equatorial cold tongue. During night-time, the equatorial undercurrent, tropical instability waves (TIWs), surface mixed layer convective turbulence, and small-scale internal waves interact with each other leading to instabilities, turbulence and therefore mixing in the stratified shears layer below the surface mixed layer, the so-called deep-cycle layer. In fall 2008, a mooring was deployed at equator 140W to capture these processes. High vertical resolution, O(1 m), and temporal resolution, O(1 s) of velocity, temperature, and salinity observations were obtained in the deep-cycle layer. Characteristics of the mixing varied with the phase of the TIW. When the meridional velocity of the TIW changed from north to south, stratification in the deep-cycle layer was relatively weak and the deep-cycle turbulence mixing was persistent following the deepening of the night-time surface mixed layer. When the meridional velocity of the TIW was southward, the stratification was strong, the surface mixed layer was shallow, and the deep-cycle turbulence mixing was intermittent. In this presentation, properties of internal wave-like features are compared, and the dynamics of instabilities in different flow phases are discussed. (Abstract ID 10886)

NEURAL NETWORK MODELING OF THE OCEAN COLOR INVERSE PROBLEM

Retrieving inherent optical properties of water from remote sensing multispectral reflectance measurements is made more difficult by the complex nature of forward modeling and the inherent nonlinearity of the inverse problem. We present here the construction and validation of three NNs working in parallel to model the inverse problem for both case 1 and case 2 waters. The first NN is used to relate the remote sensing reflectance at available MODIS visible wavelengths (412-667 nm) to the absorption and backscattering coefficients at 442 nm. The second and the third NNs output the ratio of algal to non-algal absorption and non-algal particulate to dissolved absorption coefficients respectively. Using the outputs of these statistically derived networks we can then analytically obtain the absorbing properties of the three known major water components, which include CDOM, phytoplankton, and NAP. The resulting synthetically trained algorithm was validated on both NOMAD and our own field data obtained from measurements in the Chesapeake Bay and Long Island Sound. The algorithm is also applied to two years of data collected by our Long Island Sound Coastal Observatory (LISCO). (Abstract ID 12106)
aph(555) spectra were compared to those of the diatom reference aph_diatom(λ)/aph_diatom(555) for becoming a promising approach to detect diatoms bloom from space. (Abstract ID 10920)

DETECTION OF A VARIABLE INTERNAL CI-POOL IN EMILIANIA HUXLEYI AND THALASSOSSIRA WEISSFLOGII IN RESPONSE TO CHANGES IN THE SEAWATER CARBON SYSTEM

The accumulation of an intracellular inorganic carbon pool (Ci-pool) is one strategy by which marine algae overcome low CO2(aq) in modern seawater. To determine Ci-pool accumulation prerequisites, we applied a 14C-pulse-chase method to two classes of algae. The diatom Thalassiothrix weissflogii and the calcifying coccolithophorid Emiliana huxleyi develop significant internal Ci-pools over the range 4–20 µmol/L CO2(aq). The absolute Ci-pool is related to cell size. For both algal classes the Ci-pool becomes a negligible contributor to photosynthesis once CO2(aq) exceeds 30 µmol/L. Combining the 14C-pulse-chase method and 14C-dis-equilibrium method enables us to assess whether increasing CO2(aq) results in similar thresholds for foregathering accumulation of Ci, reducing eCA activity, and reducing the reliance on bicarbonate uptake. We show a negative correlation between the Ci-pool and the proportion of CO2 satisfying photosynthetic Ci-demand. Furthermore, even when the Ci-pool of T. weissflogii disappears eCA activity is detected, implying that eCA activity is not directly related to the existence of a Ci-pool. Our new data facilitate predictions of marine phytoplankton responses to anthropogenic carbon cycle changes. (Abstract ID 9711)

INTERANNUAL VARIABILITY OF ANTHROPOGENIC AND NATURAL AIR-SEA CO2 FLUXES IN THE PACIFIC OCEAN

A better understanding of natural and anthropogenic carbon cycle is critical in determining sea surface chemical environment including ocean acidification. Besides the long term accumulation of the anthropogenic CO2 since pre-industrial era, the anthropogenic CO2 in the ocean is highly variable in interannual timescale. We have investigated the variability of air-sea CO2 fluxes using an ecosystem and carbon-cycle model combined with an ocean general circulation model. The analysis suggests that the phase relation of the interannual variations of the natural and anthropogenic fluxes depends on the regions. The variations of natural and anthropogenic CO2 flux are in phase in the central North Pacific but out of phase in the equatorial region. The different relations are caused by the differences of the regional chemical and biological responses to the climate variations. (Abstract ID 11246)

MODE WATERS: THE UPTAKE WINDOW OF NATURAL AND ANTHROPOGENIC CO2 INTO THE OCEAN INTERIOR

Is the ocean uptake of CO2 changing? And in particular, is it changing in mode water formation regions which research over the last several decades has revealed to be regions of large uptake of anthropogenic CO2? We have been measuring dissolved inorganic carbon (DIC) repeatedly at a series of hydrographic/hydrochemical station along 15°E in the western North Pacific since 1994. At 30°N for example, salinity-normalized preformed DIC (= DIC - [117/170]*AOU) shows a significant trend toward increased concentrations of order +1.1 to +0.6 µmol kg−1 year−1 on isopycnals in NPISTMW and NPCMW, respectively. The rates of increase of preformed DIC are compatible with the rate of increase of atmospheric CO2 concentrations, and indicate that the large volume of waters in these density classes...
are absorbing and transporting anthropogenic carbon from the atmosphere into the ocean interior. A preliminary analysis of pCO$_2$ from the LEDEO database [Takahashi et al., 2009] for the NPSTMW formation region in winter also shows that CO$_2$ in surface water at 25.2σ$_{θ}$ is increasing at a similar rate to that of the overlying atmosphere. **IMPACT OF AN EXTREME FLOODING EVENT IN THE HUDSON RIVER WATERSHED CAPTURED BY THE RIVER AND ESTUARY OBSERVATORY NETWORK**

Hurricane Irene passed through New York State on August 28, 2011, severely affecting the Hudson River ecosystem. The assorted automated sensors systems comprising the River and Estuary Observatory Network captured various impacts of this extreme episodic event at several locations within the Hudson River watershed. Water current increased substantially at all sites (e.g., from 30 cm/s to 2.5 m/s at Albany, NY), with water levels peaking near their historical highs. The high current briefly overwhelmed the tidal influence at a monitoring site in the Hudson River watershed and pushed the salt front downstream. Suspended sediment concentrations also increased dramatically (e.g., from 10 µL/L to 130 µL/L at Fort Edward, NY). The contribution of these extreme storm effects to the overall loading comparable to the long-term effects of sediment transport under ordinary conditions. Many climate change models predict increased severity and frequency of extreme wet weather patterns in the near future. This suggests that effects of episodic events should be considered as part of ecosystem management during activities such as navigational channel dredging, remediation projects, and long-term water usage and discharge control. **A ROLE OF THE YELLOW AND EAST CHINA SEAS ON THE DEEPENING OF WINTER MIDLATITUDE CYCLONES PASSING OVER THE EAST ASIA**

To investigate whether or not the Yellow and East China Seas (YECS) play an active role on the SLP field over the East Asia during winter, a regional numerical atmospheric model validated carefully by observed SLPs is adopted to find conditions favorable for the development of midlatitude cyclones. The modeled SLP fields demonstrate that the midlatitude-cyclone activity is moderate over the YECS because areas with the lower-level baroclinicity enhanced above these oceans are transferred as far as the shelf break of the East China Sea due to intense northerly surface winds. Based on the numerical model results, it is found that northerly surface winds weaken in accordance with the decrease of upper-level wind speeds, and that this weak surface wind condition is required for the YECS to enhance the lower-level baroclinicity. However, the lower-level baroclinicity above these oceans alone is almost incapable of developing midlatitude cyclones. It does an efficient job for the winter East Asian weather only when the lower-level baroclinicity above the YECS is enhanced concurrently with that above the YECS. (Abstract ID 10830)

**SELF-ORGANIZED SYSTEM OF JETS, WAVES AND EDDIES OFF CALIFORNIA**

The analysis of SSH altimetry observations (1992-2009) demonstrated that mesoscale flow off California presents a self-organized system containing quasi-zonal jets, bi-annual oscillations, annual and semi-annual Rossby waves as well as mesoscale eddies. This system was driven by near-resonance interactions between flow scales. Quartet (modulation) instability dominated and caused a non-local transfer of energy from waves and eddies to annual oscillations and the jets. Quartet instability required a certain level of dissipativity in the flow because it controls the number of near-resonance quadrants involved in the nonlinear energy transfer from fast to slower time scales. Inter-scale interactions stimulated phase synchronization locking at certain scales. The locking resulted in narrower and sharper mesoscale spectra, i.e. it was an effective nonlinear mechanism for scale selection and amplification. Although the quasi-zonal jets have a considerably weaker signature in SSH anomalies in comparison to Rossby waves, the jets seem to be a necessary dynamical component of ocean circulation: the jets actually act as a catalyst, helping waves and eddies to exchange energy amongst themselves. The role of jets as barriers for meridional transport in the CCS is secondary. (Abstract ID 10882)

**DYNAMIC AND THERMODYNAMIC CONTROLS OF ENSO ASSOCIATED ANOMALIES OF THE UPPER OCEAN HEAT UPTAKE IN TROPICAL PACIFIC**

The upper ocean heat budget in Tropical Pacific is evaluated using results from an ultra-high-resolution global climate simulation with a development version of Community Climate System Model (CCSM4 - HR). First, the model upper ocean hydrography and ocean mixed layer (OML) temperature budget is validated via extensive comparison with Tropical Atmosphere Ocean (TAO) observations. The model is consistent with earlier studies where the mean annual upper layer thermal balance is dominated by warming from the atmosphere and cooling by the entrainment and upwelling of deeper waters. The changes in the upper ocean heat budget during different phases of ENSO cycle are analyzed via composite analysis of the budget components. The relative role of the thermodynamic (i.e. air-sea heat fluxes) and dynamic (i.e. ocean heat advection) processes for the upper ocean heat content anomalies is evaluated. The advantages of eddy-resolving ocean for the heat budget simulation is evaluated via comparison of the model results to the lower resolution version of the model (CCSM4-LR). (Abstract ID 12623)

**BIOPROBES AND RECEIVERS IN THE OCEAN TRACKING NETWORK (OTN): GREY SEALS AS BIOLOGICAL AND OCEANOGRAPHIC SAMPLERS**

OTN Canada is a 7-year strategic research program using acoustic and other telemetry technologies to better understand species life histories and changing marine ecosystems across Canada. In the Atlantic, we are advancing the use of acoustic bioprobes: animals that carry tags which record movement paths, oceanographic data, and interactions with other tagged animals to complement measurements from fixed OTN arrays. Grey seals, which reliably return to Sable Island to breed (permitting tag recovery), allow beta-testing of VEMCO Mobile Transceivers (VMTs), coupled with Satellite-GPS transmitters, to study spatial-temporal patterns of social interactions and prey encounters by a wide-ranging, large marine predator, as well as their movements and foraging distribution in relation to fine-meso-scale seasonal oceanography in eastern Canada. Results are providing insights into foraging ecology, potential prey interactions, and predator associations at foraging grounds. Concurrently, sampled temperature and light data are being used to validate oceanographic models. With future development of fully-integrated VMTs (data uploaded in real time), this novel use of large animals as bioprobes can be extended to studying other ocean arenas and predators where tag recovery is uncertain. **A REGIONAL AIR–SEA COUPLED MODEL ADOPTED OVER THE WINTER YELLOW AND EAST CHINA SEAS**

In regions of strong sea surface temperature (SST) fronts such as Yellow and East China Sea (YES) shelves, surface winds are positively correlated with SST. In the winter YES shelves, SST is also determined by surface winds due to the surface heat flux and wind-driven ocean currents over the shallow shelves. It is therefore anticipated that SST over these areas is determined by an air-sea coupled process, and so we have established a regional air-sea coupled model to examine how SST in the YES is controlled by the coupled process. The coupled model consists of MM5 and POM. The MM5 provides POM with surface heat, freshwater and momentum fluxes, while POM gives SST as a lower boundary condition of MM5. It is interesting that the SST in the coupled model is closer to the observed one than that computed in the uncoupled POM. (Abstract ID 10838)

**VERTICAL DISTRIBUTIONS OF AGGREGATE PARTICLES AND IMPLICATIONS FOR ZOOPLANKTON FEEDING IN THE EUHOPHIC ZONE**

We have been sampling particle size distributions in conjunction with salinity, temperature, fluorescence, and backscatter in the upper 100 m of the water column off California at hourly intervals using the profiling SOLOPC float. We have been able to separate out an aggregate
component and follow its properties. The aggregate component differs from the fluorescence in its vertical distribution. There is a sharp decrease in aggregate concentration below its maximum, consistent with the particle consumption by flux feeders. We have preliminary indications of the presence of zooplankton in this region of decreasing particle concentration. Model results show quite different depth distributions of particles and zooplankton for grazing for filter feeders eating phytoplankton and for flux feeders eating falling particles. These modeling results help explain the observed vertical patterns. Our results contribute to a better understanding of processes affecting the flux of material, including carbon, out of the euphotic zone. (Abstract ID 12001)

BIO-PHYSICAL INTERACTIONS BETWEEN THE AGULHAS CURRENT AND AGULHAS BANK, SOUTH AFRICA, IN SEPTEMBER 2010

The distribution of plankton and sediments on the Agulhas Bank is highly variable and can evolve quickly, most likely due to strong coupling with the Agulhas Current and other physical processes. The Agulhas Bank is a continental shelf that extends south from the South African coast. The bank intersects the Agulhas Current, a western boundary current, to the east and the Benguela Current, an eastern boundary current, to the west. Here we examine both physical (e.g., CTD and ADCP) and biological (e.g., fluorescence and nutrient) data collected on an oceanographic cruise in September 2010 as part of the African Coelacanth Ecosystem Program (Phase II). A Natale Pulse occurred during the cruise that brought the Agulhas Current onto the Agulhas Bank. This event had significant impacts on the physical and biological processes of the eastern Agulhas Bank by sweeping plankton from the bank into the open ocean. Linear internal waves were also observed within the stratified thermocline inshore of the Agulhas Current. These waves are within the euphotic zone and appear to concentrate phytoplankton at their crest. The formation of these internal waves and the impact they have on the Agulhas Bank ecosystem will be discussed. (Abstract ID 11152)

SCALES, A NONLETHAL ALTERNATIVE TO MUSCLE TISSUE FOR OBSERVING 13C AND 15N STABLE ISOTOPES OF ATLANTIC CROAKER

Stable isotopic ratios of carbon (δ13C) and nitrogen (δ15N) were analyzed in fish scales and muscle tissue of Atlantic croaker, Micropogonias undulatus, to determine whether scales can be used as a nonlethal alternative for dietary reconstruction. Combined δ13C and δ 15N isotopic ratios can be used to investigate spatial and temporal dietary patterns of consumer species. Forty-eight juvenile Atlantic croaker were collected from estuarine habitats along the southern Texas coast. Paired analyses of muscle tissue and scale stable isotopic ratios for each fish indicated a positive linear correlation for both δ13C and δ15N. From measured δ15N values, a trophic level of 3.5 was estimated for the croaker when compared to published isotope values for common dietary items in the region. Through gut content analysis provided a shapshot of the Atlantic croaker's diet which included shrimp, isopods, crab, squid, and fish. Tissue stable isotopes provided a time-integrated measure of assimilated diets. Our results show that Atlantic croaker scales are a viable non-lethal alternative for food web studies using stable isotopic ratios to reconstruct trophic dynamics. (Abstract ID 10652)

CIRCULATION AND MIXING IN GREENLAND'S GLACIAL FJORDS INFERRED FROM PATHWAYS AND TRANSFORMATION OF GLACIALLY MODIFIED WATERS

Recent studies indicate that the ocean plays a key role in the mass-balance of the Greenland ice sheet through submarine melting of outlet glaciers. These glaciers drain the ice sheet into deep, strongly stratified fjords, many of which are characterized by a subsurface layer of warm, Atlantic-origin water. Greenland's glacial fjords cannot be explained by traditional paradigms because significant density modification and forcing occurs at the glacier front from melting and from the addition of glacial runoff. Despite the importance of understanding the oceanic heat transport to glaciers, little is known about the basic dynamics of such fjords. Here we use hydraulic surveys of two fjords in southeastern Greenland (Sermilik and Kangerdlussuaq fjords, which drain Helheim and Kangerdlussuaq glaciers, respectively) collected from 2008 to 2011, together with continuous records from moored instruments, to identify glacially modified waters and trace their evolution into the ambient stratification. We then use these export pathways of glacially modified water to diagnose the circulation and mixing patterns within the fijords. (Abstract ID 10693)

TURBULENCE CONTROL OF FLOC SIZE IN THE RIVER-ESTUARY TRANSITION ZONE (RETZ)

The RETZ plays a significant role in the formation and evolution of flocs whose properties vary on short temporal and spatial scales. Quantifying floc properties and floc dynamics in relation to the physical forcings is key in determining the transfer flux of SPM from the catchment to the coastal ocean. The transfer of SPM in the RETZ is a result of advection, resuspension and aggregation related to turbulence and salinity. Variations in the turbulence regime are one of the main determinants of floc properties, thereby having significant control on the fate of the transfer of terrestrially derived organic matter to the coastal ocean. PREDICTABILITY OF FROGENESIS FILMAMENTS IN THE MIXED LAYER

One class of submesoscale features are upwelling filaments along the boundaries of eddies, and these features are on the order of 10 to 20 km across and hundreds of kilometers in length while persisting for days to weeks. The initial conclusion would be that these features are unobservable by typical observations and would be entirely unconstrained in ocean model predictions. However, the mechanism generating these filaments is frontogenesis involving the geostrophic flow advecting horizontal buoyancy gradients creating an ageostrophic upwelling that thrusts the mixed layer (initially described by Hoskins and others related to atmospheric frontogenesis). Because generation is deterministically linked to the mesoscale eddy field, these unobservable filaments are generated in the same locations if the eddy field is positioned correctly. A series of observation system simulation experiments is conducted with a 3km resolution ocean model from June 2004 through December 2005, a time with four operating altimeter satellites allowing for evaluation of relative error levels in deterministic and nondeterministic processes. The results show the frontogenesis filaments are reproducible if the mesoscale field is constrained. Dramatic effects on acoustic propagation are also demonstrated. (Abstract ID 11227)

POPULATION GENETICS OF DEEP-SEA LIMPETS FROM HYDROTHERMAL VENTS IN THE SOUTHWESTERN PACIFIC

Hydrothermal vents are discrete and ephemeral habitats that support chemosynthetic communities. Marine invertebrates ensure gene flow and dispersal from one location to another through larval and other dispersive life-history stages. Barriers or filters that might impede dispersal include behavioral adaptations at local scales and, at regional scales, advection by deep-sea currents, obstruction by geomorphological features, and isolation by distance between sites. This study used partial sequences of the mitochondrial gene cytochrome oxidase 1 (COI) to test for population structure and gene flow at multiple spatial scales in the limpet species Oligasaris tommanni collected from Manus and Lau Basins (~3500 km apart) in the SW Pacific. Within Manus Basin, we tested for population structure within and among three discrete sites at scales ranging from a few meters to approximately 40 km. COI haplotypes were analyzed to determine nucleotide diversity, haplotype diversity, Tajima's D values, and pairwise FST. No evidence for genetic differentiation was detected at any spatial level considered. These findings suggest that the gene flow among O. tommanni populations is uninhibited within Manus Basin and between Manus and Lau Basin. (Abstract ID 10274)

Copper is essential for the nitrogen cycle, being required for the enzymes associated with nitrous oxide and nitrite reduction and the first step in nitritation, ammonium oxidation. Recent studies have suggested that the demand for copper may be particularly high in some ammonium oxidizing archaebacteria, which also employ copper-dependent mechanisms for other processes. The organic speciation of copper was characterized in the eastern tropical South Pacific Ocean (ETSP), which is the site of one of the world’s largest oxygen minimum zones, and in Washington’s Hood Canal from late January to early March 2010 and in July 2011, respectively. Results indicate that free copper is exceedingly low in zones of high nitritation activity. In the ETSP, free Cu was much lower within the primary nitrite maximum than anywhere else, including the underlying, reducing oxygen minimum zone. This study compliments other work to study the Cu requirements associated with denitrification. The goal of these studies was to investigate the relationship between ammonium oxidation and the concentration of bioavailable copper. (Abstract ID 9942)

INTENSIVE STUDY OF SWELLS IN THE SEMI-ENCLOSED SEA USING NUMERICAL MODEL AND MEASUREMENT DATA.

Abnormally large swells occurred on the coast of the East Sea on February 24, 2008 and caused a loss of three lives and also damaged several west coasts of Japan. The East Sea is semi-enclosed sea bounded by the west by Korea and on the East by Japan, and swells generated in the center of the East Sea are well recorded with time shift at both coasts. By analyzing these intensive wave observation data and wave prediction model results, detailed swell characteristics can be studied in the East Sea. SWAN model is tested with measurement data of wave directional spectrum as well as frequency spectrum for accurate forecasting of swells in terms of time and location. Transformation of swells from the center of the East Sea to the coasts are examined and used for the alarm system for large dangerous swells. Specially, wave directional spectrum comparison between model results and observation data finds the origin of swells. This study also introduces swell warning system being operated on the west coast of Korea. (Abstract ID 11265)

ZOOPS-O: A COMBINED WIDE-BAND ACOUSTIC AND OPTICAL ZOOPLANKTON IMAGING SYSTEM.

To obtain abundance estimates of zooplankton in the upper 500 meters a new wide-band acoustic-optic imaging system has been developed. The system uses (4) sonar transducers that produce sound in the range of 1.5 – 2.5 MHz whose data is augmented with monochrome optical images from a system that uses a shadowgraphic technique. Wide-band acoustic offer superior range resolution (~1.5 mm) with the additional potential to measure organism thickness. High transmit power and low-noise receive electronics permit reflections from superior range resolution (~1.5 mm) with the additional potential to measure organism concentration of bioavailable copper. DISOLVED IRON REDOX CHEMISTRY IN THE OXYGEN MINIMUM ZONE (OMZ) OF THE COSTA RICA UPWELLING DOME.

Disolved Fe and Fe(II) concentrations were measured in the Costa Rica upwelling dome along with oxidation rate studies of Fe(II) in the surface seawater and oxygen minimum layer in July 2010. The OMZ is a well-demarcated feature characterized by high rates of denitrification, and a deep nitrate maximum coinciding with oxygen levels below 1 mmol L-1. A Fe(II) maxima as well as a total dissolved Fe maxima coinciding with the secondary nitrate maximum and oxygen minimum layer was observed. The presence of a surface Fe(II) maxima was also reported. During the oxidation rate measurement studies, the OMZ Fe(II) signal behaved similarly to the added Fe(II) signal whereas the surface Fe(II) signal did not behave like the added Fe(II). Addition of EDTA led the OMZ Fe (II) signal to decay rapidly, the surface Fe(II) signal did not. This leads us to believe in the authenticity of the OMZ Fe(II) signal whereas the surface water signal could be a “tolumin- reactive” species. These results specify the importance of Fe redox status in understanding the relationship between nitrogen cycle and Fe distribution in the ocean. (Abstract ID 9958)

ANNUAL DYNAMICS OF CARBON TO CHLOROPHYLL RATIO IN TEMPERATE COASTAL WATERS.

The seasonal patterns in the phytoplankton carbon to chlorophyll ratio (C:Chl) was analyzed in samples collected from 22 stations during 1990 to 2009. A total of 6100 samples were included in the analysis. C:Chl values were lowest during winter and displayed approximately the same values of about 12 regardless of season. During the spring season C:Chl increased and reached maximum summer values between 25 and 80 depending on the station. The maximal C:Chl values were highest at the open water stations and lowest at the estuarine stations. After the maximum summer values, the C:Chl returned to the general winter value of 12 in the early winter. The maximal C:Chl varied with environmental variables. The best correlation was found for C:Chl and the average annual mean total nitrogen concentration. A simoidal model was fitted by month to C:Chl to predict C:Chl from observed annual mean total nitrogen concentrations. We also show an increase in summer C:Chl of 1 during the past 20 years corresponding to reductions in nitrogen loadings as a result of national action plans to reduce nutrient loadings (Abstract ID 11993)

MONITORING THE DIFFUSE ATTENUATION COEFFICIENT KD IN OPEN AND TURBID WATERS FROM OCEAN COLOR IMAGES USING A NEURAL NETWORK INVERSION.

The fine-scale study of the diffuse attenuation coefficient, Kg(λ), of the spectral solar downward irradiance is only feasible by ocean color remote sensing. Several empirical and semi-analytical methods were developed for the past three decades. However, most of these models are generally applicable for clear open ocean waters. They show limitations...
Waves and currents measured on a steep, reflective beach

A field experiment was performed on Carmel River State Beach, CA in June-July, 2011, to examine cross-shore exchange processes on a steep, reflective beach without subaerial bars, using a cross-shore array of co-located pressure and velocity sensors. The beach profile consisted of a 1:7.6 subaerial beach slope, 1:3 subaqueous beach step, and 1:19 subaqueous beach profile. The reflection (R) of shoreward surface gravity wave energy is approximately 0.65 for the sea-swell (0.05-0.15 Hz) frequency band, which increases for low amplitude, long period swell waves. Excluding long period waves, T > 11s, most of the E-variability is tidally related, which cannot be explained by changes in the beach profile steepness. The vertical structure of the cross-shore and alongshore currents associated with the “large swash zone” currents are similar to observations within dissipative “surf zones.” The undertow profile directly outside of wave breaking is non-existent. However, further offshore, the vertical velocity structure is similar to dissipative beaches and increases with increasing wave energy. The effect of wave reflection on cross-shore exchange will be presented. (Abstract ID 10221)

Recent observations of warm and saline under-ice cross-shore transport on the Laptev Sea shelf

The Laptev Sea shelf is strongly impacted by the Lena River freshwater runoff and is an important ice formation and export region. In 2009, anomalously warm and saline waters likely with basin origin, were distributed over the shelf and changed the hydrography for > 1 year. In early 2010, oceanographic moorings recorded the arrival of the anomalies on the inner shelf in form of a near-bottom under-ice gravity current, as a response to offshore winds and ice drift. Sea ice linked with winds and currents, allows insight into the processes leading to cross-shelf and vertical transport. For instance, near-shore polynyas and enhanced ice drift in early winter lead to lateral and vertical buoyancy fluxes, mixing and redistribution of fresher surface waters.

Despite ice formation, bottom waters became less dense, which is opposite to the commonly observed dense water formation in other polar regions. Once landfast ice had established, ice drift was limited towards offshore, and currents were governed by near-bottom onshore flow. Our observations show a vigorous under-ice circulation with implications for heat and nutrient budgets on the Laptev Sea shelf. (Abstract ID 10165)

Comparison of Bed Roughness and Hydrodynamics Observations for Four Tropical Reefs

Since the rugosity of coral reefs remains unchanged over hydrodynamically relevant timescales, measurements of fixed-bed roughness can be more suitable for modeling wave and current processes than the variable wave friction factor and hydraulic roughness typically obtained from water column observations. However, in coral reef environments, there are no dependable parameters that can relate physical length scales with hydrodynamic roughness scales. To further our understanding of the relation between seabed roughness and hydrodynamic processes, we have carried out observations of fixed-bed roughness, wave and current characteristics around four tropical reefs in Oahu and Palau. The reefs have diverse levels of bed roughness and are exposed to different wave and current forcing, ranging from high wave energy on Oahu’s North Shore to very low energy on Palau’s west coast reef lagoon. High resolution fixed-bed roughness measurements were collected using a narrow beam altimeter mounted on an AUV, while hydrodynamic observations were obtained using a combination of bottom mounted and AUV-based acoustic instruments. Here we focus on the AUV-based roughness measurements and address the spatial structure of the hydrodynamic response. Spectral and cluster analysis techniques are employed to try to identify relevant length scales that could be related to the hydrodynamic response through mechanisms such as wave dissipation and current boundary layer structure. Snapshots of mixing over the East Flower Garden Bank under different flow conditions

The East Flower Garden Bank (EFGB) is a coral reef located near the shelf edge in the northeastern part of the Gulf of Mexico, and it is a part of the Flower Garden Banks National Marine Sanctuary managed by the National Oceanic and Atmospheric Administration. Major and minor axes of the bank are aligned with the longitude and latitude, respectively. The bank top rises from water depths of 100 – 130 m to about 18 m below the sea surface. In June and August 2011, the Naval Research Laboratory collected microstructure observations over the bank. Several sections, mainly along the minor axis, were completed to evaluate the spatial structure and strength of mixing under different flow conditions. These observations indicate that mixing strength and its spatial distribution depend strongly on the currents. For the similar flow conditions, the largest energy dissipation rates and eddy diffusivities were always found on the lee side of the bank. The strength of mixing was well correlated with current speeds. Weak currents, as those observed in August, were accompanied by significantly subdued mixing over the EFGB. (Abstract ID 10356)

Demographic control in Mnemiopsis leidyi population dynamics revealed by high frequency observations

Growing attention has focused on frequent outbreaks of gelatinous carnivore zooplankton observed in coastal areas worldwide. Although these phenomena might have broad ecological implications, the triggering mechanisms of both the onset and the end of such events remain equivocal. Here we examine daily variations of the ctenophore Mnemiopsis leidyi abundance and its relation to environmental conditions and food availability. The period investigated encompasses the beginning and the decline of the population outbreak. We show a sharp succession in the population size structure and that the rate of change in developmental stages correlates with food availability, temperature and salinity. Concurrent with the population ageing (i.e. dominance of adult stages and large sizes) the zooplankton abundance markedly dropped. This is followed by an enhanced decline of M. leidyi abundance that increases along with the population size structure and strength of mixing under different flow conditions. These observations indicate that mixing strength and its spatial distribution depend strongly on the currents. For the similar flow conditions, the largest energy dissipation rates and eddy diffusivities were always found on the lee side of the bank. The strength of mixing was well correlated with current speeds. Weak currents, as those observed in August, were accompanied by significantly subdued mixing over the EFGB. (Abstract ID 10356)

EFFECTS OF REDUCED SUMMER SEA ICE ON WALRUS DISTRIBUTION AND BENTHIC FORAGING PATTERNS

The Pacific walrus feeds on benthic invertebrates of the continental shelf and rests upon sea ice between foraging trips. However, the lack of sea ice over the Chukchi Sea shelf in recent summers has caused female and young walruses to use coastal resting grounds for periods of up to three months. We used satellite telemetry data to compare movements and foraging patterns of walruses using coastal haul-outs during ice-free periods with those of walruses using offshore sea ice haul-outs when ice was present. Walruses swim greater distances to prey patches when using coastal haul-outs than when using offshore sea ice. Both near shore and offshore foraging generally occurred in areas of high benthic biomass, but foraging associated with coastal haul-outs in northwest Alaska occurred in the coastal domain where the relative abundance of preferred prey and benthic production is low. These changes to walrus distribution and foraging patterns likely affect their bioenergetic and population growth and are a direct effect of sea ice loss. (Abstract ID 10764)

SEPARATING DECADAL-SCALE FLUCTUATIONS FROM LONGER-TERM TRENDS IN TIDAL PROPERTIES

Extraction of secular trends in tidal properties from tidal records has more in common with determination of mean sea level (MSL) trends than simply use of the same data. Both require ~50yrs of data to extract a valid trend and/or trend acceleration, and both suffer difficulties in trend extraction due to limited length of record (LOR) and the presence of multiple-scale “noise.” The simplest remedy is to lengthen the record. Thus, we have recovered data from 2-18 yr records from the mid-19th Century, and there are ~1500 station-years of tidal data in the Pacific and North America to be recovered. For extracting tidal trends, nodal cycle variability can be removed using admittances. Analysis then show a significant correlation between admittance and MSL anomalies that are (in part) related to climate fluctuations. Exploration of fluctuations in tidal properties on decadal time scales is vital, because their removal improves trend extraction, and because this exercise provides insight to the causes of secular trends. Finally, empirical mode decomposition provides a convenient method for separating scales of variability and defining trends. (Abstract ID 12045)

TRACING THE CIRCULATION AROUND FUKUSHIMA

Following the release of radioactive isotopes from the Fukushima nuclear power plants, we undertook a cruise to sample the ocean waters off the eastern coast of Japan. As part of this effort, 24 surface drifters were deployed and subsequently tracked. The trajectories of these drifters indicate that much of the contaminated water was being pulled away from the coast on the northern side of the Kuroshio Extension. However, some of the drifters stayed in the coastal region suggesting that some contaminated water may recirculate in this area before being washed off-shore. The absence of drifter crossings across the Kuroshio Extension core suggests that it inhibits the southward spreading of contaminated water, at least over the western Pacific ocean. Measurements of different radioactive contaminants seem to agree with our interpretation based on drifters. Using the drifter trajectories, we test and validate methods to extend the tracking back to the initial releases and into the future to track the fate of the contamination. (Abstract ID 10759)

THE WOODS HOLE PARTNERSHIP EDUCATION PROGRAM: INCREASING DIVERSITY IN THE OCEAN AND ENVIRONMENTAL SCIENCES IN ONE INFLUENTIAL SCIENCE COMMUNITY

A consortium of public and private institutions created the Woods Hole Partnership Education Program, or PEP, in 2008. Participating institutions are the Marine Biological Laboratory, Northeast Fisheries Science Center of NOAA/AS National Marine Fisheries Service, Sea Education Association, U.S. Geological Survey, Woods Hole Oceanographic Institution, the Woods Hole Research Center, and University of Maryland Eastern Shore. Aimed at college juniors and seniors, PEP is a four-week course and a six-to-eight-week individual research project under the guidance of a research mentor. Investigators from the science institutions serve as course faculty and research mentors. We listened to experts regarding critical mass, mentoring, adequate support, network recruitment, and built a program based on those features. We have a program that works with its own model for choosing applicants and for matching with mentors. We continue fine-tuning our matching process, enhancing mentoring skills, preparing students for a variety of lab cultures, and setting expectations high while remaining supportive. Our challenges are to keep it at, using leverage instead of capacity to make a difference. Collaboration, not competition, is key since a rising tide floats all boats. (Abstract ID 12171)

THE EFFECT OF OIL AND DISPERSED OIL ON MICROBIAL PRODUCTION AND CARBON FLOW

Oil from the Deepwater Horizon spill may have competing effects on microbial production in the Gulf of Mexico. On the one hand, oil may serve as a dissolved organic carbon source and might stimulate bacterioplankton production, especially by those organisms capable of direct degradation of hydrocarbons. In contrast, oil and dispersed oil may be directly toxic to microorganisms, both autotrophic and heterotrophic. Both of these processes may change microbial community structure and alter biogeochemical cycles. Direct effects of oil and dispersed oil on bacterioplankton (3H-leucine incorporation) and phytoplankton production (14C-bicarbonate production) were examined. In addition, we examined the effect of oil and dispersed oil on extracellular release of carbon by phytoplankton and subsequent uptake by bacterioplankton in three locations in the northern Gulf of Mexico. In general, phytoplankton production was more sensitive to oil and dispersed oil than was bacterioplankton production. While oil reduced carbon fixation, it had minimal effect on extracellular release of fixed carbon but bacterioplankton took up less of the released carbon, perhaps as a result of substrate
competition with oil carbon. (Abstract ID 10651)

FROM LAB TO LAUNCH: INTEGRATING BIOMARKERS DERIVED FROM GENOMICS AND PROTEOMICS APPROACHES INTO REMOTE OBSERVING PLATFORMS

Genome-scale data from phytoplankton has rapidly increased in the last decade as a result of new sequencing technologies and funded efforts to sequence organisms important in marine biogeochemical cycles. More recently, new technologies are being used to profile expressed genes and proteins in biogeochemically important organisms under conditions that influence productivity and export (e.g. nutrient limitation). These methods provide an unbiased approach to identify biomarkers that can be used to indicate the physiological status of an organism in the environment. By taking advantage of the ability of phytoplankton to sense their environment, these methods can also be used as potential sensitive indicators of in situ chemical conditions. As remote observing systems come online, these methods can be combined with high throughput measurements of ocean chemistry and cell enumeration technologies to profile biological response over unprecedented temporal scales. We will discuss examples of potential biomarkers identified using new sequencing methods and speculate on approaches for integrating these into remote observing platforms. (Abstract ID 11862)

COUPLED MODELING OF AIR-SEA INTERACTION IN THE INDIAN OCEAN DURING MJO EVENTS IN 2009

Application of a regional fully coupled atmosphere-ocean-wave modeling system (COAMPS) to the spring and fall of 2009 onset of the Wytville jet in the Indian Ocean is discussed. The atmospheric model covers the tropical Indian Ocean with a resolution of 27 km with an inner nest covering the area from 66°E to 85°E, 10°S to 5°N with a higher resolution of 9 km. The ocean model is the Naval Coastal Ocean Model (NCOM) with a 1/8° horizontal resolution, and 60 vertical levels. Using 0.5 m resolution in the upper 10 m enables the ocean model to have a well defined diurnal cycle in the mixed layer and capture barrier layer variability. Strong zonal easterly winds along the equator, associated with the Madden-Julian oscillation, cause the diurnal cycle of sea surface temperature to vanish and provide strong vertical mixing. Compared to global models such as the Navy Operational Global Atmosphere Prediction System (NOGAPS) for the atmosphere and the Global Navy Coastal Ocean Model (G-NCOM) for the ocean, the models used to provide lateral boundary conditions, agreement with observations is significantly improved. IMPACTS OF OCEANIC CURRENTS ON THE M2 INTERNAL TIDE IN THE EAST/JAPAN SEA

The M2 internal tide in the East/Japan Sea is investigated using a high resolution numerical model (RIAM Ocean Model) which has been used for the real-time ocean forecasting system of the East/Japan Sea at RIAM. The model assimilates satellite-measured sea surface temperature and height every day, which produces realistic background fields of oceanic current and stratification. It includes tidal forcing estimated from NAO.99b regional ocean tide model along open boundaries. The study period is from September 2005 to August 2009. Surface tides reproduced in the model agree well with in situ measurements from coastal tidal gage, satellite altimetry, shipboard ADCP across the Korea/Tsuchima Straits, HF radar, and current moorings in the Ulleung Basin. Annual average of the first-mode M2 internal tidal energy computed using numerical model outputs is consistent with previous observation in the Ulleung Basin. Monthly-mean patterns of M2 internal tide distribution reveal close relationship with changes of background current and stratification fields. We present the impact of background fields on the energy transfer from barotropic to several modes of baroclinic M2 tide in the East/Japan Sea. (Abstract ID 10889)

NEW FINDING OF THE NORTH EQUATORIAL UNDERCURRENT IN THE WESTERN PACIFIC OCEAN

Currents obtained from moored ADCPs were analyzed from October 2007 to May 2011. Three subsurface moored buoy systems are located approximately across the Subtropical Countercurrent (STCC), near the northern boundary of, and at the center of the main axis of North Equatorial Current (NEC), respectively, in the western Pacific Ocean. Under the prevailing westward-flowing NEC, the eastward-flowing STCC and the North Equatorial Undercurrent (NEUC) sometimes appeared in the surface and in the subsurface layers, respectively, with an intra-seasonal time scale. While STCC appears as the result of vertical shear in the STCC-NEC system due to local wind stresses, NEUC seems to appear as the result of the combination of equatorial current system and local geostrophic balance. However, it needs more systematic survey whether NEUC is totally fed from the convergence of the Luzon and Mindanao Undercurrents or not, what drives NEUC in a variable intra-seasonal time scale and how far it continues to flow eastwards, and under what condition it disappear in the western boundary region and so on. OPEN OCEAN INFRARED AND NEAR-SURFACE OBSERVATIONS OF SST SPATIAL VARIABILITY

Open ocean observations of SST spatial variability have been limited by several challenges. Airborne measurements using infrared cameras can provide rich detail but are generally limited to coastal regions. Ship-based measurements can cover large distances but are generally limited to one-dimensional samples along the ship track. To overcome these limitations, a balloon-based infrared camera system known as LTARS (Lighter-than-Air Remote Sensing) is deployed with a towed near-surface CTD system known as SSSP (Surface Salinity Profiler) for deployment on the open ocean. This unique combination of measurements will be evaluated on a transit leg from W. Samoa to Hawaii, where conditions of low wind and high solar insolation are likely to result in significant spatial variability. Spatial scales of SST variability will be investigated using infrared images of roughly 100 m x 100 m and near surface temperature profiles from 0 to 2 m depth taken simultaneously for extended periods along the ship track. The Alaska Department of Environmental Conservation (ADEC) and University of Alaska School of Fisheries and Ocean Sciences, Fairbanks (SFOS), established an Alaska Monitoring and Assessment Program (AKMAP) focused on conducting aquatic-resource surveys of Alaska’s waters. ADEC and SFOS conducted research cruises in the fall of 2010 and 2011 to survey and monitor the state of the Chukchi Sea coastal environment. The purpose of this survey was to assess the water quality and ecological status of waters of the northeastern Chukchi Sea, from Pt. Hope to Barrow, in waters 10–50 m in depth. The 2-year survey was conducted aboard the R/V Nornen II. We sampled 64 stations with the following methods: grab; beam and otter trawls; biological-contaminant samples; and sediment- and biological-isotope samples. We also conducted surveys for marine birds and mammals during transit between stations. The AKMAP assessment estimated the spatial extent of water quality based on stressors such as contaminants, water-quality parameters, and upper trophic level taxa. Findings are anticipated to be available by late 2012. (Abstract ID 9774)
VIRUS-MEDIATED TRANSFORMATION OF ORGANIC CARBON IN THE SURFACE WATER OF THE WESTERN PACIFIC

Marine viruses are known as consumers of their host microbes while viral lysis can release dissolved organic carbon (DOC) into the water as carbon sources for the survived populations to grow up for next cycle. To investigate the effects of this ‘double-edged-sword’ in the field, simulated in situ incubation experiments with natural microbial communities were conducted in the Western Pacific. Initial samples were filtered with 0.2 μm filters and then ultra-filtered (>30KDa) to obtain virus stocks and virus-free filtrates. Incubations were added with natural host bacteria and/or viruses, or added with inactivated-viruses as control. Bacteria, viruses and DOC were monitored for 7 days during the incubation time courses. The results showed that the net increases in bacterial production (BP) in the incubations with active viruses were the highest. Although the host bacteria were subject to high mortality due to viral lysis, BP may be stimulated by viral lysates. Meanwhile DOC concentrations fluctuated but finally increased by the end of the incubation, suggesting somewhat accumulation of refractory-like DOC in the systems. (Abstract ID 10994)

SEASONAL VARIATION OF EDDY SHEDDING FROM THE KUROSHIO INTRUSION IN THE LUZON STRAIT

Altimeter data and output from the Hybrid Coordinate Ocean Model global assimilation run are used to study the seasonal variation of eddy shedding from the Kuroshio intrusion in the Luzon Strait. The results suggest that most eddy shedding events occur from December through March, and no eddy shedding event occurs in June, September, or October. About a month before eddy shedding, the Kuroshio intrusion extends into the South China Sea and a closed anticyclonic eddy appears inside the Kuroshio loop which then detaches from the Kuroshio intrusion. Anticyclonic eddies detached from December through February move westward at a speed of about 0.1 m/s after shedding, whereas eddies detached in other months either stay at the place of origin or move westward at a very slow speed (less than 0.06 m/s). The HYCOM outputs and QuikSCAT wind data clearly show that the seasonal variation of eddy shedding is influenced by the monsoon winds. A comparison between eddy volume and integrated Ekman transport indicates that once the integrated Ekman transport exceeds 2 × 10¹² m³ (which roughly corresponds to the volume of an eddy), the Kuroshio intrusion expands and an eddy shedding event occurs within one month. We infer that the Ekman drift of the northeasterly monsoon pushes the Kuroshio intrusion into the SCS, creates a net westward transport into the Strait, and leads to an eddy detachment from the Kuroshio. (Abstract ID 9467)

DISSOLVED ORGANIC CARBON IN EDICARAN-EARLY CAMBRIAN OCEAN

The size and fate of the dissolved organic carbon (DOC) reservoir in late Neoproterozoic oceans and its relationship with the unusual paleoceanographic events remain debated. One of the uncertainties is the temporal evolution of an inferred DOC reservoir orders of magnitude larger than that of the modern ocean. Paired carbonate and organic C-isotope data from the Ediacaran-early Cambrian succession in south China reveal repetitive occurrences of depleted to coupled carbonate-organic C-isotope signatures at the basal Ediacaran (ca. 635 Ma), middle-late Ediacaran (>515 Ma), and basal Cambrian (ca. 542 Ma). In contrast, following these intervals organic C-isotopes are mostly stable. The C-isotope patterns suggest repetitive growth rather than terminal oxidation of the marine DOC reservoir in Ediacaran-early Cambrian oceans. Compilation of existing iron and sulfate data suggests episodic increase of sulfate and iron concentration in proximity of the negative C-isotope excursions but significant drop in iron, sulfate, and other trace element concentrations between these excursions. This phenomenon suggests that the episodic growth of DOC reservoir in Ediacaran-early Cambrian oceans was possibly driven by the switch from sulfate to iron reduction of organic matter in the ocean. The termination of significant DOC growth may have been associated with fundamental changes in marine ecosystems and the sulfate reservoir, which did not happen until the end of early Cambrian (<520 Ma). (Abstract ID 12390)

COUPLED CIRCULATION AND BIOGEOCHEMISTRY MODELING SYSTEM IN THE CHINA SEA BASIN-SHELF-EstuARY INTERACTION

Semi-enclosed marginal South China Sea and shelf seas of Bohai, Yellow and East China Seas are linked together by Taiwan Strait to form the China Seas (CS). It connects with western Pacific Ocean by shelf break and Luzon Strait, and with terrestrial inputs by big Changjiang and Pearl River estuaries. The circulation in the CS is mainly driven by the south-east Asia monsoon, but largely modulated by intrusive current from Kuroshio on seaside, by buoyancy from the estuaries on landside and by highly variable current associated with flow-topography (effect) interaction over the shelf. This circulation imports chemical constituents of different properties from land and open ocean basin, mixes with waters in the CS and forms an active biogeochemical response. A new three-dimension, coupled physics-biogeochemistry modeling system, which dynamically links processes of heterologous biophysical characteristics and of different spatiotemporal scales in the marginal sea, shelf and estuary of the CS, has been developed to hindcast/forecast the regional ocean circulation and biogeochemical processes. The modeling results are scientifically validated and improved by our seasonal interdisciplinary field measurements, and more importantly by dynamic understanding of Kuroshio-Sea interaction, variable potential vorticity and momentum balances over shelf topography, interactive estuary-shelf process and their associated biogeochemical responses. EROSIONAL FEATURE EVOLUTION OF FINE SEDIMENTS—CASE STUDY IN THE MODERN YELLOW RIVER DELTA, CHINA

This study was conducted in July 2008 to investigate the sediment erosional features and sediment properties of the modern Yellow River delta at 5 selected sub-deltaic lobes formed respectively in 1929, 1934, 1938, 1976, and 1996. Two typical study areas were selected to carry out detailed physical simulation experiments using a self-designed wave-producer device and a circulating flume in order to reveal the effects of wave loading on sediment erodibility. Sediments deposited in the study site derive from material sourced on the Loess Plateau region. However, going through different deposition history in marine environment, unique local characters appear in the sub-deltaic lobes formed at different times. This suggests that modifications occur in the deposits due to age and diagenesis leading to mechanical properties better resisting erosion, along with the decrease in fine-particle content, increase in sand content, and variation in physical properties of sediments. In the two sites where detailed experiments were conducted it was also observed the important role of the wave loading in changing the erodibility of the deposit. This is in part associated with a partial redistribution of the particles with finer ones moving upward from the underside of seabed and removed by flows. This may lead to increased erodibility of the changed deposits but the increased erodibility can be easily loosened under wave loading actions. (Abstract ID 11046)

THE IMPACT OF AMBIENT STRATIFICATION ON FRESHWATER TRANSPORT IN A RIVER PLUME

The influence of ambient stratification on the river plume dynamics is studied numerically using ROMS. The shell flow is thermally stratified and retains a 15-m deep upper mixed layer. A buoyant inflow into the model domain is systematically varied in order to obtain buoyant plumes with different vertical structure. Surface-advected plumes spreading on top of the pycnocline are affected by the stratification. Bottom-advected plumes on the other hand deepen the pycnocline which in some cases triggers the instabilities. Initially, the formation of a frontal disturbance occurs downstream of the estuarine bulge, with more eddies developing later along the entire density front. More eddies develop either with a smaller inflow salinity anomaly or with a stronger stratification, while eddies are less developed with a gentler bottom slope. Frontal eddies triggered by the ambient stratification reduce up to 35% the freshwater flux in downstream direction and enhance it in the offshore direction compared to the corresponding nonstratified case. Energy transfer diagnostics indicate that eddies are likely to be produced through the baroclinic instability of the buoyancy-driven current. (Abstract ID 11294)

SEASONAL VARIATION OF EDDY SHEDDING FROM THE KUROSHIO INTRUSION IN THE LUZON STRAIT

The HYCOM outputs and QuikSCAT wind data clearly show that the seasonal variation of eddy shedding is influenced by the monsoon winds. A comparison between eddy volume and integrated Ekman transport indicates that once the integrated Ekman transport exceeds 2 × 10¹² m³ (which roughly corresponds to the volume of an eddy), the Kuroshio intrusion expands and an eddy shedding event occurs within one month. We infer that the Ekman drift of the northeasterly monsoon pushes the Kuroshio intrusion into the SCS, creates a net westward transport into the Strait, and leads to an eddy detachment from the Kuroshio. Jiang, Q., University of Nevada Las Vegas, Las Vegas, USA, Gangqing.Jiang@unlv.edu
for the East China Sea and Changjiang Estuary has been established, which is comprised of three-domain WRF model and unstructured-grid FVCOM model with the implementation of FVCOM-SWAVE and FVCOM-SED modules to include full physical wave-current-sediment interactions. The unstructured triangle grids not only have the capability for excellent geometric fitting for irregular coastlines and steep topography, but also provide the common-grid method to make domain nesting with mass conservation guaranteed. The core FVCOM model of ECS-CE system contains three sub-models, including East China Sea FVCOM, Changjiang FVCOM and Deep Waterway FVCOM, to consider the regional shelf-scale Kuroshio Current, estuary-scale Changjiang Plume and local-scale small-size eddies within the groynes and dike in the river mouth. The model system has been validated with the observation data of surface wind, tide, wave, current and salinity to reveal correct dynamics around the ECS and CE. The model system is demonstrated with two realistic applications around the Changjiang Estuary, including a strong typhoon impact and the summertime saltwater intrusion within the North Passage of the CE. LINKING PHYSICAL AND MICRABIAL OCEANOGRAPHY THROUGH PICOPLANKTON EXPORT TO THE DARK OCEAN

Photrophic picoplankton are the major contributors to primary production in the surface ocean, but are overlooked in the deep-sea carbon studies as they are known to be present only in the euphotic zone and are thought to be unsinkable due to their tiny cells. However, we observed abundant planktonic autocorvohphages including Prochlorococcus, Synechococcus and pico-eukaryotes at the depths of 200–2000 m in the South China Sea off the Western Pacific, during 2008-2011. Internal solitary waves and meso-scale eddies are found to be mainly responsible for the transportation of photrophic picoplankton to the dark ocean. Unlike the known mechanisms such as sinking of phytoplankton and aggregates or grazing-mediated transport, our findings suggest a novel mechanism for rapid vertical transportation of picoplankton carbon to the dark ocean where the picoplankton cells are subjected to strong viral lysis that will not only provide carbon sources to the microbial loop but also contribute to the microbial carbon pump through which the organic carbon is ultimately transformed to refractory phase carbon sequestration. VALIDATION OF CESM ICE-OCEAN MODEL IN THE ARCTIC: UPPER OCEAN THERMOCLINE AND SEA ICE

The heterogeneous sea ice cover, strong haloline and various boundary currents present major challenges to climate modeling in the Arctic Ocean. The results of CESM ice ocean model (POP-CICE) run forced by NCEP reanalysis CORE2 data from 1992-2007 are analyzed and compared with ocean and sea ice observations. Besides validating against ocean temperature and salinity climatology and remote sensing sea ice area and extent, we also picked several time series of observables to check the seasonal cycle of the model performance and upper ocean mixing process. The observational data sets include SHERA 1997-98, and ice based profiling buoys (ITP, J-CAD and POPS) in 2000s are used to validate the simulated upper ocean temperature and salinity profiles and their changes from 1990s to 2000s. Sea ice drift, submarine and moored ULS measurements of ice thickness distribution are compared to sea ice model results. Several model experiments with different configurations of background viscosity diffusivity coefficients and with/without sub-grid scale brine rejection parameterization scheme we developed recently are discussed. Since this is an ongoing study, summary of conclusion will made at the presentation time. (Abstract ID 12451)

CONTRIBUTIONS TO LARGE-SCALE SEA LEVEL CHANGES IN THE NORTH ATLANTIC OCEAN

Large-scale sea level in the North Atlantic region is studied by using sea surface height (SSH) from the TOPEX/POSEIDON/JASON altimeters and wind stress curl from the QuikSCAT scatterometer and from the European Center for Medium-Range Weather Forecasting (ECMWF). We model SSH changes owing to heating and wind forcing. The steric response to heating shows an annual cycle at low to mid latitudes. On interannual times scales surface heating is an important contributor to SSH anomalies in the eastern basin and is correlated with the North Atlantic Oscillation (NAO). Surface heating contributes to interannual changes, as seen in the first Empirical Orthogonal Function of SSH. Non-steric SSH consists of wind-forced anomalies from westward propagating waves south of 20N, from the baroclinic Sverdrup balance in the subtropics and from the topographic Sverdrup balance in the subpolar. The mean current path from the topographic Sverdrup balance tends to follow the Gulf Stream and the Azores Current, rather than the North Atlantic Current, implying the topographic Sverdrup is important west of the Mid-Atlantic Ridge and the Gulf Stream is constrained by both winds and topography. DOWNSCALING LONG-TERM VARIABILITY OF SUBSURFACE THERMAL STRUCTURES OT REGIONAL SCALES IN THE SUBPOLAR NORTH ATLANTIC

The subsurface temperature anomaly (STA) were estimated using a multi-linear regression method based on the relations between changes in sea surface height anomaly (SSHA) and sea surface temperature anomaly (SSTA). The multi-linear regression coefficients in different depths were computed using monthly mean Argo data from 2005 to 2010 and applied to satellite altimetry and SSTA measurements from 1993 to 2010 to obtain STA for the same time periods. Then, the large scales of estimated STA and SSHA variability were downscaled to different scales using ensemble empirical mode decomposition method. We found that 1) STA warming trends and associated dominant frequencies are geographically different in the Labrador Sea and the Irminger Sea, resulting from interactions of different water masses from the Arctic Sea and the Gulf Stream, and 2) the decomposed time scales of SSHA and SST showed the southward coastal Kelvin waves, associated with the deep water formations in the Labrador Sea. It suggests that the coastal Kelvin waves generated in the Labrador Sea can be detectable in the regional scales of SSHA in the Mid-Atlantic Bight. (Abstract ID 12208)

PARTNERING TO BUILD THE GULF OF MEXICO COASTAL OCEAN OBSERVING SYSTEM

The Gulf of Mexico Coastal Ocean Observing System (GCOOS) is designed to empower people, communities and businesses with data and information to improve their decision-making about our lives, work, and play within a healthy ecosystem along the Nation’s Gulf Coast. GCOOS is being built through a partnership of many entities—federal, state, and local governments, academia, NGOs, and private industry—engaging together to provide a sustained, integrated, operational network of observations, data and products for the greater benefit of our society. The GCOOS build-out began in 2007 through integration of an initial set of existing federal and non-federal resources and the development of the GCOOS Data Portal. Using results of discussions with a wide range of stakeholders on their needs for data, information, and products about the Gulf of Mexico, its resources, and its ecosystem, the key elements of the GCOOS Build-Out Plan were determined. The initial system is being enhanced by the integration of additional existing resources into the GCOOS, and the installation of new assets to fill the observational gaps identified in the GCOOS Build-Out Plan. GLACIAL- INTERGLACIAL CHANGES TO THE AIR-SEA CARBON FLUXES: THE EQUATORIAL HYPOTHESIS

When forced with insolation from 115.000 years ago the new Community Climate System Model (version9) is able to reproduce ice and snow build-up that matches the reconstructions
in pattern and magnitude. We used this model together with the CCSM land and ocean biogeochemistry modules to understand the causes for the 100ppm difference in atmospheric carbon dioxide concentration between 115ka and preindustrial times. As suggested by the proponents of the Southern Ocean Hypothesis CCSM does indeed show a reduced Southern Ocean outgassing when forced with 115ka insolation. This is compensated by increased outgassing in coastal upwelling zones, so that CCSM does not reproduce the observed drop in atmospheric carbon dioxide concentration. However, by replacing the diffusivity based background mixing in the CCSM ocean model with an energy based mixing, we can reproduce the observed drop of approximately 1ppm in 100 years. It is shown that the increased tropical insolation 115 ka leads to an increased tropical stratification which inhibits the diffusion of dissolved inorganic carbon across the equatorial thermocline. This leads to an increased accumulation of abyssal carbon and reduced outgassing along the equator in general, but the equatorial Pacific in particular. We propose to replace the current paradigm of the Southern Ocean Hypothesis with this Equatorial Hypothesis. (Abstract ID 9306)

NEAR-INERTIAL WAVE DRIVEN MIXING AND CLIMATE

Oceanic uptake in the fully coupled Community Earth System Model (CESM) is addressed through improved representation of near-inertial (NIW) driven mixing. This dynamic control is needed to better resolve some of the observed differences between observed and simulated key property distributions in the ocean, including CFCs. A novel technique to account for the underrepresentation of NIW energy input from wind through a simple modification of the K-Profile Parameterization (KPP) of ocean boundary layer mixing is developed for the latest version of CESM, as well as a parameterization for the NIW induced mixing beneath the mixed layer. The most important impact is a deepening of the mid-latitude mixed layers, and this increased model sensitivity to atmospheric storms increases the thermocline ventilation. The increase in ventilation and mixed layer depth represent a significant improvement of CESM and lead to a more realistic uptake of greenhouse gases in global warming scenarios. Furthermore, NIWs alter the Arctic temperature and nutrient concentration responses to global warming, because the loss of sea ice exposes the Arctic to more NIW induced mixing. (Abstract ID 12172)

VARIATIONS OF THE DENMARK STRAIT OVERFLOW

Dense water enters the North Atlantic as overflows across the Greenland-Scotland Ridge, where the passage in Denmark Strait is the widest gap. The velocity of the Denmark Strait overflow has been measured in the Strait with two current profiling moorings since 1999 (with several interruptions). The calculated overflow transport exhibits variations on all time scales. Eddy variability dominates the high frequency variations, while interannual variability masks any possible long term trends. Only seasonal variations were found to be of no significance, in contrast to modeling results. The mean overflow transport is 3.3 Sv. Since 2006 data from moored temperature, conductivity and pressure recorders is available as well, monitoring the hydrographic variations of the overflow. In recent years the temperature time series of the Denmark Strait overflow revealed a cooling, while the salinity stayed nearly constant. Events of increased temperatures at the mooring location close to the Icelandic shelf indicated occurrences of Atlantic water intrusions. The deep flow therefore seems to be not independent from the upper ocean variability; the migration of the Inninger Current induces reduced overflow events. (Abstract ID 9695)

THE BIOLOGICAL FRACTIONATION OF Fe ISOTOPES BY THE DIATOMS T. PSEUDONANA AND T. OCEANICA IN CULTURE

Iron is an important nutrient for life in the ocean, where low Fe concentrations often limit the growth of marine phytoplankton. Fe stable isotope ratios (δ56Fe) are a potentially valuable new tool to study the marine biological cycling of Fe. However, parameters such as the isotope effect for Fe acquisition by phytoplankton must be quantified in order to most effectively use δ56Fe as a tracer for biochemical processes in the ocean. We have measured the biological fractionation of Fe isotopes for the marine diatoms T. pseudonana and T. oceanica in culture. Phytoplankton were cultured in EDTA or NTA buffered media under varying Fe concentrations from Fe-sufficiency to Fe-limitation. Biological fractionation of Fe isotopes was determined by comparing δ56Fe in the media to filtered phytoplankton. The use of a cell wash allows us to distinguish between isotopic fractionation during extracellular adsorption and intracellular uptake. The biological fractionation of Fe isotopes is highly dependent on culture conditions with δ56Fe ranging from -0.1 ‰ to +0.6 ‰ depending on ligand composition, species, and Fe-limitation status. (Abstract ID 11620)

DETECTION OF FISH BILE METABOLITES BY FLUORESCENCE FROM THE NORTHERN GULF OF MEXICO DEEPWATER HORIZON OIL SPILL

In April-July 2010, the Deepwater Horizon spill released almost 5 million barrels of crude oil into the Gulf of Mexico (GOM). Crude oil is composed of many compounds, including polynuclear aromatic hydrocarbons (PAHs) that fish metabolize and excrete in bile. Bile PAH metabolites can be detected and quantified via fluorimetry to assess PAH and oil exposure. From June 2010 to May 2011, several hundred commercially and recreationally harvested fish including Lutjanus campechanus (Red Snapper), Pagrus pagrus (Red Porgy), and Seriola fasciata (Amberjack) were collected from reefs along the Alabama and Florida coasts. Bile and livers were frozen until analysis. Bile was diluted in methanol and fluorescence was measured at excitation/emission wavelengths of 290/335, 341/383 and 380/430 nm to detect metabolites of 2, 4 and 5 ring PAHs, respectively. Samples were standardized to biliverdin and protein concentrations. Most fish had fluorescence signals consistent with naphthal (a metabolite of naphthalene) in bile indicative of oil exposure. Bile concentrations, in naphthal equivalents, ranged from 30-4000 μmol/l. Additional research on biochemical responses to oil exposure in these fish is ongoing. (Abstract ID 10561)

RELATIVE CONTRIBUTIONS OF TEMPERATURE AND SALINITY TO SEASONAL MIXED LAYER DENSITY CHANGES AND HORIZONTAL DENSITY GRADIENTS

Temperature and salinity profiles from the Argo Program allow construction and analysis of a global, monthly mixed layer climatology including the effects of temperature and salinity on density. Temperature changes dominate the seasonal cycle of mixed layer density in most regions, but salinity changes are dominant in the tropical warm pools, the Arctic, and the Antarctic. Under the IFZ-C temperature and salinity work in concert to effect the seasonal density changes. In the eastern subtropics seasonal salinity changes partially compensate those in temperature. The times of maximum and minimum mixed layer density exhibit regional variations. For instance, the equatorial region is better aligned with Southern Hemisphere timing, and much of the North Indian Ocean has a minimum density in May and June. Outside of the tropics, the maximum mixed layer density occurs later in the winter, and the minimum earlier in the summer, approaching the poles. At the times of maximum mixed layer density, some, but by no means all, of the ocean has horizontal temperature and salinity gradients that
work against each other to reduce the horizontal density gradient. (Abstract ID 9732)

**HOW PRECISELY CAN NET COMMUNITY PRODUCTION BE OBSERVED USING OXYGEN SENSORS ON PROFILING FLOATS**

Robust biogeochemical sensors, such as oxygen, simple bioptics and nitrate, now make it feasible to build a sensor network based on profiling floats that could operate on a global scale, similar to the Argo array. A global, biogeochemical network could monitor processes such as Net Community Production (NCP), carbon export to depth, transport of nutrients into the upper ocean, and inter-annual changes in the volume of suboxic water in the ocean. A community based effort to develop such a system, called GLOBE (Global Ocean Biogeochemical Experiment), is proceeding. Critical to the design of such a system and its scientific goals is an understanding of how precisely and accurately these processes can be observed. Continuous records of oxygen on profiling floats operating near Hawaii are now available for 10 years and nitrate records are available for four years. Here we use these records to assess the temporal variability in NCP near Hawaii. Our results indicate that oxygen sensors can constrain NCP to within 15% at the 95% confidence level, if the sensors are properly calibrated. (Abstract ID 10069)

**UNDERSTANDING OCEAN CHEMISTRY AND BIOLOGY USING REAL-TIME DATA FROM PROFILING FLOATS**

Real-time data play an important role in science education by adding relevance to the learning experience, by enabling self-discovery and inquiry, and by providing opportunity for dialogue between students and researchers (Adams and Masumoto, 2011). Over the past decade, profiling floats (such as Argo) have proven to be excellent platforms for deployment of biogeochemical sensors. Data are available year round and sensors clearly resolve seasonal cycles. Seasonal changes in phytoplankton biomass, uptake of nitrate as an essential fertilizer, and the production of oxygen can all be observed. A global distribution of profiling biogeochemical floats allows students and teachers to contrast processes in the tropics with events at high latitudes. Data streams from profiling floats are well defined, enabling simple, point and click interfaces, such as FloatViz (http://www.oao.obs-vlfr.fr) or OAO (Oceanographic Autonomous Observations, http://www.oao.obs-vlfr.fr/). Examples using data easily accessed from the classroom will be presented. As networks of biogeochemical floats expand, the types of lessons will also expand. We will present our vision for incorporating using data easily accessed from the classroom will be presented. As networks of biogeochemical floats allows students and teachers to contrast processes in the tropics with those that relate to flexion. We extracted data from multiple species across divergent lineages in order to quantify the extent that propulsors exhibit flexile tendencies at or near their tips. Our results indicate an aggregate grouping of the values within restricted ranges for both the flexion angle and the inflection ratio, with low standard deviations within the samples. More studies must be done to evaluate further flexile-scale patterns of propulsor flexion; however, this data suggests that biological propulsion has converged upon similar limits for organisms inhabiting different fluid environments. (Abstract ID 10516)

**OBSERVATIONS OF MESOSCALE EDDIES NEAR THE BERMUDA ATLANTIC TIME SERIES STUDY SITE AND IMPLICATIONS FOR THE LOCAL HYDROGRAPHY AND NUTRIENT BUDGETS**

Significant long term change in the hydrography of the upper ocean at the BATS site has been documented and appears to be locally forced. However, diagnosed changes in the depth integrated heat and salinity budgets over the sampling period can be much greater than the time integrated surface fluxes. This imbalance is likely due to mesoscale eddies meandering through the local region. BATS cruises typically have a small spatial component often highlighting the extent of this associated eddy variability in the surface mixed layer and underlying STMW. For example, STMW has been observed to vary from the more conventional 200m kbps to non-detectable over distances of 80km while mixed layer depths can vary by greater than 100m over similar distances. We analyze these spatial data in the context of SLA fields and demonstrate that closure of the local hydrography and nutrient budgets over monthly periods can be improved on consideration of upstream initial conditions. Comparisons with hindcast data from ocean assimilation models are also performed to assess the feasibility of a more robust approach for estimating advection at BATS. (Abstract ID 12498)

**INVESTIGATION OF THE HYPOXIA TOLERANCE OF BLUE CRAB (CALLINECTES SAPIDUS)**

The Chesapeake Bay, one of the world’s largest estuaries, is currently experiencing hypoxia and anoxia. The Bay is the habitat for many organisms, including the blue crab. It was conceived that blue crabs were oxygen consumers and we unable to handle low oxygen environments. Using a respirometer, a crab’s metabolic rate was measured in low oxygenated water. The goal of the research was to identify the critical PO2 where the crab begins anaerobic breathing. Crabs that have been infected with the parasite Hematodinium were also used in the experiments because the disease is extremely prevalent in the species. Through this work, it was concluded that crabs are in fact, oxygen regulators above critical oxygen saturation. Metabolic rate can be increased by Hematodinium infection, feeding, and raised temperature. This research is critical to understanding blue crab conservation and the importance of habitat restoration. (Abstract ID 10851)

**THE MOLECULAR DIVERSITY AND BIOGEOGRAPHY OF PROCHLOROCoccus, THE DOMINANT OPEN OCEAN PHOTOSYNTHETIC MICROBE**

The marine cyanobacterium Prochlorococcus is the most abundant photosynthetic microbe in tropical and subtropical open oceans and accounts for 5-25% of global marine primary production. This genus is comprised of two major clades, one that is high-light adapted and numerically dominant near the surface and a second clade that is low-light adapted and dominantly deeper in the euphotic zone. However, among these major groups, there are at least 7 genetically distinct clades that have unique environmental distributions and hence are considered ecotypes. Here we report on the distribution of these groups over vast regions of the Pacific and Atlantic Oceans using large scale pyrosequencing, aPCR and metagenomics-based approaches. We show that these distributions are structured along major environmental gradients such as temperature and light, but that there also exists significant molecular diversity within these clades that may further niche partition along theo...
The interpretation of the carbon isotopic composition of sedimentary carbonates and organic matter are central to our understanding of Earth history. For instance, Neoproterozoic carbonates contain dramatic negative isotopic anomalies within long intervals (100-1000 million years) of enriched compositions (roughly 5 permil). Classically, the isotopic composition of carbonates can be linked to atmospheric oxygen accumulation through the stoichiometry of primary production and subsequently, a tight coupling between the isotopic composition of carbonates and organic matter is expected. However, the demonstrable lack of isotopic covariance in Neoproterozoic successions has inspired alternative models for the operation of the Neoproterozoic carbon cycle: one such model posits the presence of a large marine reservoir of dissolved organic carbon (DOC). Here we present carbonate and organic carbon isotopic data from Mongolia, northwest Canada and Namibia that provides an alternative to the large DOC model. Importantly, these data and a new quantitative treatment do not preclude the presence of DOC in the ocean, but simply offer an additional mechanism for producing the observed records. TUNA-DOLPHIN-BIRD FEEDING ASSEMBLAGES IN THE GALAPAGOS ISLANDS AND THEIR RESPONSE TO THE PHYSICAL CHARACTERISTICS OF THE UPPER WATER COLUMN

Tuna-dolphin-bird feeding assemblages are unique to the Eastern Tropical Pacific Ocean (ETP) and may be associated with oceanographic features. In the Galapagos Marine Reserve (GMR), intra-annual and interannual changes affect these features in the area, inducing mesoscale and fine scale temporal variability which may control the locations of these groups. Data were collected during three four-week cruises between the mainland of Ecuador and the GMR and one small boat survey within the GMR between September 2008 to October 2010. Marine mammal surveys were conducted during daylight hours and CTD casts were taken regularly. Data were analyzed to compare physical features of the water column to the sighting locations. Additionally, these data were used to predict where tuna would be most likely to associate with the presence of DOC in the ocean, but simply offer an additional mechanism for producing the observed records. MULTIPLE JETS AND DENSITY FRONTS IN AN IDEALIZED MODEL OF THE SOUTHERN OCEAN

The density structure of the Southern Ocean exhibits persistent multiple fronts with steep isopycnal slopes, which extend from the surface to the abyss. We use an idealized, eddy-permitting model with simple geometry and surface forcing to investigate the formation and maintenance of multiple density fronts in the Southern Ocean. Tilted isopycnals in the circumpolar current are baroclinically unstable, leading to eddy mixing of potential vorticity (PV) in the jet flanks. Using transformed Eulerian mean theory, we demonstrate that the resulting eddy-induced circulation locally sharpens PV fronts in the upper water column. At depths, eddies tend to homogenize PV along isopycnal surfaces, establishing vertically coherent density structures and strongly coupling horizontal and vertical stratification. These findings provide insights into the relationships between surface fronts, the interior PV distribution, and eddy-induced transports. (Abstract ID 11832)

BIOPHYSICAL-STATISTICAL MODELING: A QUANTITATIVE METHOD FOR ADDRESSING UNCERTAINTY IN MARINE BIOGEOCHEMICAL MODELS.

Traditionally, deterministic models have encapsulated our knowledge of specific biogeochemical (BGC) processes, however, as our knowledge of physiological and systems processes increases, so too has the complexity of these models. This has resulted in an explosion in the number of unobservable, and in many cases, highly uncertain parameters. Many studies have questioned our ability to constrain these models given the spatio-temporal sparsity of observations, which often differ from the state variables being modeled. Bayesian Hierarchical Modelling (BHM) offers a robust statistical framework that embraces process models, whereby model error, parameter uncertainty and observation error are quantitatively represented through the use of probability distributions, hence Biophysical-Statistical Modeling. We have applied the BHM framework to a relatively simple BGC model, and investigate the uncertainty in the predicted state and parameters and identify what combinations of observations are required to adequately constrain the state and parameters in different environmental conditions. THE EFFECT OF ENCRUSTATION ON THE TRACE ELEMENT COMPOSITION OF N. DUTERTREI IMPLICATIONS FOR RECONSTRUCTING PAST SEA WATER TEMPERATURE

Deep-dwelling planktonic foraminifera often develop a calcite crust when reaching a certain temperature during descent in the watercolumn at the end of their lifecycle. The composition of this layer considerably influences the whole test chemistry and therefore Mg/Ca-based reconstructions of past seawater temperature. We have determined intra- and intertest element variability of Neogloboquadrina dutertrei from sediment trap and sediment samples of modern and glacial age from the SW Indian Ocean. Trace element profiles confirm the presence of a low Mg/Ca and Mg/Ca crust covering the chambers. Crust thickness and composition vary systematically over the chambers, indicating a tight biological control, independent of temperature, on precipitation of this crust. Sediment data indicate that a significant part of the Holocene-Glacial change in whole-chamber Mg/Ca is due to changes in the composition of the crust. Conversion to temperature adds disproportional weight to these relatively minor Mg/Ca changes, thereby biasing the inferred Holocene-Glacial contrast. Similar mechanisms probably apply to other crust-forming foraminifera, thus highlighting the need to better understand crust formation and trace element incorporation for improved reconstructions of temperatures. EVALUATION OF SOUTHERN OCEAN O2/AR-BASED NCP MEASUREMENTS IN A MODEL FRAMEWORK

The sea-air biological O2 flux assessed from measurements of surface O2 supersaturation in excess of Ar supersaturation (bioflux), is increasingly being used to constrain net community production (NCP) in the upper ocean mixed layer. In making these calculations, one generally assumes that NCP is at steady-state, mixed layer depth is constant, and there is no O2 exchange across the base of the mixed layer. The object of this project is to evaluate the magnitude of errors introduced by violations of these assumptions. Therefore, we examine the differences between the sea-air biological O2 flux and NCP in the Southern Ocean mixed layer as calculated using two ocean biogeochemistry general circulation models. In this approach, true NCP is known from the prognostic model and biological O2 flux is calculated from the models biological O2 supersaturation and the gas transfer velocity. We find that biological O2 flux gives an accurate picture of the regional-scale patterns and trends in NCP. However, on local scales violations of assumptions lead to significant, non-uniform differences between model NCP and biological O2. (Abstract ID 11270)

RECONSTRUCTION OF THE DEEPWATER HORIZON OIL SPILL AND ITS POSSIBLE IMPACT IN MEXICAN COASTS AND WATERS

Based on the information of the amount of oil budget reported by the Federal Interagency Solutions Group and using a hydcast simulation with the Hybrid Coordinate Ocean Model (HYCOM) and a forecast simulation with the Weather, Research and Forecasting (WRF) model, a reconstruction of the oil concentration and its evolution along the period April 20-December 31, 2010 is done. The daily COAPS-FSU ocean circulation hyndcast was used for the ocean currents and the 3-hour winds from the numerical forecast of CCA-UNAM. Particular interest is considered on the concentrations in Mexican coasts and waters. (Abstract ID 11918)

CLUSTER ANALYSIS OF WHITE SHARK DIVING PATTERNS: LINKING DISTINCT BEHAVIORAL MODELS TO OCEANOGRAPHIC PROCESSES

Tracking top predators in relation to oceanographic variables provides valuable insight into how their distribution correlates with a changing environment. However, understanding the underlying physical processes that predators are responding to requires knowledge of specific behavior such as foraging, mating or transiting. We used diving behavior of white sharks Carcharodon carcharias to discriminate between specific patterns linked to different environmental processes in the Northeastern Pacific. White sharks exert a substantial top-down effect on coastal ecosystems, particularly on pinipeded populations, but little is known of their importance in oceanic ecosystems where they spend a substantial amount of time. We applied clustering analysis to Pop-up Archival Satellite transmitted summary records to identify
dive modes exhibited throughout the Northeastern Pacific range. We found four distinctive behavioral clusters validated by previously described behaviors. We mapped behavior mode occurrence in space and time, and illustrate an important link between this apex predator and the deep scattering layer. This method can be broadly applied to tracking data to improve causal links between oceanographic variability and animal life history processes. (Abstract ID 12537)

ACOUSTIC BACKSCATTERING FROM ROUGH SURFACES

When investigating properties of the seafloor using acoustic techniques, small-scale (sub-acoustic wavelength) variations of the topography can have a significant impact on the reflected acoustic field. If the effects of these variations, termed roughness, are not incorporated in a physical model, then there can be introduced a bias in inversions for seafloor topography and properties. A single interaction of a sound wave with a rough sea floor will be modeled here, with the aim of demonstrating the effects of roughness on the scattered acoustic field. A finite element model and a model based on the Kirchhoff approximation from optical scattering will be presented, as well as a discussion on the importance of three-dimensional roughness scattering. A RE-EXAMINATION OF LIGHT LIMITATION AS A KEY FACTOR LIMITING PHYTOPLANKTON PRODUCTIVITY IN THE SOUTHERN OCEAN.

The influence of available macronutrients, iron and light in controlling primary production in the Southern Ocean are well established. In the Southern Ocean (~ >60s) light limits production in winter whereas Fe has been thought to be the main driver of the high nutrient low chlorophyll (HNLC) conditions found in summer. Exceptions occur at frontal regions, near islands and the marginal ice zone where enhanced stratification and increased iron supply alleviate iron and light stress. The nature of the interplay between iron and light limitation of phytoplankton productivity however remains open to debate. We use high resolution 802/ Ar data sets collected in the austral summers of 2007 – 2010 to investigate the response of net community production (NCP) to surface ocean mixed-layer dynamics. NCP observations from underway 802/Ar show a remarkable relationship with corresponding MLD and reveal the hitherto underexamined factor of light limitation as the main cause of the variability of net community production in the Southern Ocean. These findings and the derived relationships provide potentially useful constraints to rapidly developing process capabilities in biogeochemical models. (Abstract ID 11145)

BARUM, IRON, COPPER, NICKEL, MANGANESE, COBALT AND NUTRIENT DISTRIBUTIONS IN THE WATER COLUMN AFFECTED BY THE DEEPWATER HORIZON OIL SPILL.

The impact of the oil spill on trace element and nutrient distributions was examined with data from early and late May and October 2010. Positive relationships between nutrient and DON anomalies in the subsurface plume (1000-1400 m depth) suggest the effect of microbial oil/gas consumption. In surface waters, metal-salinity relationships suggest a dominant river influence. In the subsurface plume, elevated metal concentrations were observed during late May. However, separating the inputs from crude oil, dispersant, drilling mud, and bottom water resuspension as well as biological removal is problematic. Correlation with percent methylmercaptan in the plume indicates the increased Co is due to leaching from crude oil. Spatially, Ba and Cu showed a peak within 10 km of the wellhead. Correlation between Ba and Cu anomalies and their low concentrations in the crude oil suggests that these elements were likely derived from drilling mud. We also observed a decreasing trend of Fe toward the wellhead, suggestive of uptake; however, the data can also be interpreted as indicative of benthic Fe input with the trend towards the wellhead being topographically-controlled. BLOGGING FROM SEA

Student and professionally prepared blogs are being incorporated into the website of Sea Education Association (www.sea.edu). Transmitted daily from sailing research vessels at sea with classes of undergraduate students, these blogs include descriptions of scientific results and life aboard the vessels. This information is presented through daily slideshows, frequent video blogs and static content with scientific background information and links to other resources. Daily still images and blogs are produced by students describing their personal research and at-sea experience. Expanded video content on two cruises, Plastics at Sea, North Atlantic Expedition and Energy and the Ocean Environment, was fully produced and edited at sea by a dedicated videographer. Transmitted by satellite, these materials are incorporated into the SEA web page by a shore based staff member. These blogs have proven effective in translating the experience of research and discovery at sea to a wide audience as well as provide an effective means of providing accurate data in an accessible way to a large audience. User feedback, including journalists using these materials for their work, has been enthusiastically positive. (Abstract ID 1051)

EXAMINATION OF THE INFLUENCE OF THE PATH OF KURUSHO ON MERIDIONAL EDDY TRANSPORT OF SENSIBLE AND LATENT HEAT IN THE TROPOSPHERE.

Previous studies of the relation between interannual changes in the path of the Kuroshio and Gulf Stream on the synoptic variability of the wintertime (FWM) atmospheric boundary layer (Joyce, Kwon, and Yu 2009) have been augmented by inclusion of the Oyashio path and extended into the troposphere using MERRA atmospheric reanalysis for the 24 year period of 1983-2006, inclusive. In addition, we have analyzed the intra-seasonal (8-90d) contribution of the transient eddy fluxes in the atmosphere as well as the synoptic band (2-8d). We find that at mid-latitudes, approximately 2/3 of the thermal flux in the atmosphere is due to sensible heat and 1/3 due to moisture. The intra-seasonal and synoptic bands contain approximately equal contributions to the vertically-integrated transient eddy signal, although they have distinctly different spatial characteristics. While the statistical dependence of atmospheric fluxes on path shifts of the Gulf Stream and Oyashio has been carried out, in this report we will focus on the relationship with the interannually-changing path of the Kuroshio Extension, which represents the most significant hemispheric influence of the ocean on the atmosphere. Accounting for as much as 10% of the record’s winter mean, zonally-integrated, transient thermal energy transport in the mid-latitude troposphere. (Abstract ID 9881)

SOME NEW PERSPECTIVES ON EIGHTEEN DEGREE WATER FORMATION

Evolving ideas of Eighteen Degree Water (EDW) formation will be discussed including two quite different hypotheses on its formation by Worthington and Warren. Worthington’s concept of EDW formation was that it represented a shallow type of mean meridional overturning in the NW Atlantic in which tropical/subtropical characteristics of the near surface waters of the northereasterly-flowing Gulf Stream (GS) were transformed by intense air-sea exchange and returned southwards as a colder, denser water mass. Warren argued that since annual mean heat losses in the region occupied by EDW to the south of the GS were small, EDW was merely renewed locally with advection being unimportant. A recently completed field study of EDW (CLIMODE) is indicating that EDW formation within a given winter can have at least two different dominant physics and distinct locations: one type formed in the Sargasso Sea, largely away from the strong flows of the GS where 1D physics may apply, and a second type formed along the southern flank of the GS, in a region where the background vorticity of the flow and cross-frontal mixing plays a key role in the convective formation process. Because the latter process occurs within the GS frontal zone, cross-frontal fluxes of heat and salt can play a significant role in the GS mode of EDW formation, and impart different water mass characteristics compared to the EDW formed away from the GS in the Sargasso Sea. INTENSE SEDIMENTATION TO THE SEAFLOOR FOLLOWING THE 2010 MACONDO BLOWOUT: GEOCHEMICAL COMPOSITION, MECHANISMS, AND MICROBIAL IMPACTS.

From April to July 2010, 4.5 to 6 million barrels of oil were released into Gulf of Mexico waters from the Macondo Blowout. Two million gallons of chemical dispersant were applied at the wellhead and sea surface to reduce the amount of oil deposited in the coastal zone. While the ultimate fate of the released oil remains debated, some fraction was deposited to the seafloor in a substantial pulse that occurred between June and September 2010. Concentrations of petroleum biomarkers and unresolved complex mixtures in seafloor samples were 2–10 times higher in September 2010 than in May 2010, with polyacrylamide hydrocarbons more abundant to the northwest of the wellhead. These results are consistent with the hypothesis that much of the released oil was deposited at the seafloor. The role of dispersants versus microbial processes in stimulating oil sedimentation were examined in laboratory experiments and both appear to play a role in oil sedimentation. Samples collected during a summer 2011 cruise are being analyzed to further identify and quantify microbiologically-mediated transformations of the oil-derived organic matter in these sediments. (Abstract ID 12777)

MULTISCALE AND MULTIPHASE LAGRANGIAN MODELLING OF THE RADIOACTIVITY DISPERSION IN THE SEA AFTER ACCIDENT AT THE FUKUSHIMA NPP.

The Lagrangian multiphase model of the radionuclide transport in the sea is applied to simulate dispersion of radioactivity released from Fukushima daiichi NPP due to the accident. The particle-tracking model describes transport and transfers of radioactivity between water, suspended and bottom sediments. The sediment transport model simulates deposition and re-suspension of non-cohesive, cohesive sediments and mixture of fractions of different size of cohesive/non-cohesive sediments. The Pacific Ocean currents are simulated using MOM3 model with resolution whereas coastal transport processes are described by coastal circulation model with high resolution. A number of scenarios of radioactivity release were simulated and results were compared with available observations of radionuclide concentrations. It was concluded that main problems in predicting radioactivity dispersion in the Fukushima NPP case are (i) correct estimation of source including air deposition and coastal run-off and (ii) accurate prediction of local currents because they are driven here by highly variable currents governed by Kuroshio/Oyashio system. The Fukushima NPP accident clearly demonstrated need in integrated regional system of forecasts of radioactivity dispersion in air, ground and marine environments to be used in comprehensive decision-support systems. (Abstract ID 9829)

SPATIAL STRUCTURE OF SIPHON FLOWS

The Siphon model of Mackay et al. (2009) is used to parameterize Siphon flows. The Siphon model is based on work by Marmoro (1976) and develops an algorithm for experimentally measured Siphon flows. The model is also used to investigate the effect of pipe diameter, pipe length, and pipe inclination on the flow. The model is validated against experimental data and shows good agreement.

Suction into capillary tubes (aka siphon flow) is widely used to create fluid dynamic stimuli in zooplankton experiments, induce bioluminescence in phytoplankton and measure mechanical properties of fibers and phytoplankton chains, as well as sample water. Many suspension feeders produce similar flows. For typical applications, flow just inside or just outside the capillary opening is of most interest. As climate change alters the vertical distribution of turbulence intensities, quantified flows will be even more important tools for experimentation. Uniform flow at a capillary entrance is almost universally assumed, becoming parabolic downstream. Entrance length is the distance from the entrance where axial velocity reaches 99% of its peak value. This entrance-length solution is very much like the drunk looking for keys under the streetlamp it is easily calculated but not very relevant. External, these same flows have been characterized as point, spherical sinks. The two idealizations conflict. Finite-element modeling in COMSOL Multiphysics (COMSOL, Inc., Burlington, MA) shows that both are particularly inaccurate at low pipe Reynolds numbers (Re). In general, entrance lengths are shorter and decay distances of velocities outside the capillary are longer than the idealizations suggest, and uniform entrance velocity is a poor approximation. External flows also vary widely but predictably in flow direction with Re. (Abstract ID 10981)

MICROBIAL IMPACTS.

The modelling system for oil spills consists of the oil spill model, circulation and wave forecast model with resolution whereas coastal transport processes are described by coastal circulation and wave model with high resolution. The Fukushima NPP accident clearly demonstrated need in integrated regional system of forecasts of radioactivity dispersion in air, ground and marine environments to be used in comprehensive decision-support systems. (Abstract ID 9829)

MASONCO BLOWOUT: GEOCHEMICAL COMPOSITION, MECHANISMS, AND MICROBIAL IMPACTS.

From April to July 2010, 4.5 to 6 million barrels of oil were released into Gulf of Mexico waters from the Macondo Blowout. Two million gallons of chemical dispersant were applied at the wellhead and sea surface to reduce the amount of oil deposited in the coastal zone. While the ultimate fate of the released oil remains debated, some fraction was deposited to the seafloor in a substantial pulse that occurred between June and September 2010. Concentrations of petroleum biomarkers and unresolved complex mixtures in seafloor samples were 2–10 times higher in September 2010 than in May 2010, with polyacrylamide hydrocarbons more abundant to the northwest of the wellhead. These results are consistent with the hypothesis that much of the released oil was deposited at the seafloor. The role of dispersants versus microbial processes in stimulating oil sedimentation were examined in laboratory experiments and both appear to play a role in oil sedimentation. Samples collected during a summer 2011 cruise are being analyzed to further identify and quantify microbiologically-mediated transformations of the oil-derived organic matter in these sediments. (Abstract ID 12777)
simulation showed quite well agreement. The simulations showed that even in the conditions of domination of tidal currents the wind and Stokes drifts play important role in the oil spill propagation. Therefore accurate prediction of the currents and waves is crucial for oil spill response actions. (Abstract ID 9830)

Determination of accurate ocean surface fluxes of heat, freshwater, and momentum is pivotal for understanding and modeling air-sea interactions. Oceanic reanalyses have been very useful in evaluating models, but the quality of these products has often been questioned for specific type of applications. Meteorological variables gained from ocean buoy stations and a fixed platform (leeds) in the Yellow Sea, East China, and East/Japan Seas are used to calculate the latent and sensible heat fluxes with COARE flux algorithm 3.0 (Fairall et al., 1996). The buoy-derived fluxes are compared with five atmospheric model reanalyses (NCEP1, NCEP2, CFSR, INTERIM, MERRA) and objectively analyzed data (OAflux). The Taylor diagram is used to assess which products are closer to those estimated from buoy data. Cross correlations are higher than 0.7 for all products mainly due to the strong seasonality. In terms of the standard deviation, the performance of the products is better in an order of MERRA-OAflux-INTERIM-CFSF-NCEP1-NCEP2. This order of performance is nearly same for all stations and different time scales such as synoptic (3-15days) and intraseasonal (1-4months) scales. More details on the evaluation of the reanalysis products will be presented. (Abstract ID 12844)

Abstract: Copepod nauplii are often the most abundant metazoans in pelagic ecosystems, and they can be important players in food web dynamics. However, little is known about the ecology of nauplii due to the challenges associated with quantitative sampling and identification to species. Here we present a quantitative real-time PCR (qPCR) based approach to identifying and enumerating copepod nauplii in field populations. We use DNA copy number of the target gene, mtCOI, in size-fractionated environmental samples to infer the number of nauplii present in the population. Laboratory experiments on DNA extraction methods, species-specificity of qPCR amplification, qPCR inhibition, changes in DNA copy number across developmental stage, and a direct comparison between the qPCR approach and microscopic enumeration of copepod nauplii have been completed in order to establish the accuracy of the method. Our initial work focuses on Parvocalanus crassirostris, a common planktonic copepod in subtropical coastal ecosystems. This approach will allow us to investigate population responses to environmental perturbations across all developmental stages, and could be extended to study other micro-metazoans in the sea. (Abstract ID 12605)

On the continental margin of central Oregon, upwelling, biological productivity, and remineralization drive tremendous variability in biochemistry over a range of spatiotemporal scales. In an effort to better understand the interplay between seasonal and event-scale dynamics, biological metabolism, and coastal carbon chemistry in this region, we deployed a shallow-water Slocum glider in conjunction with a larger-scale hydrographic survey of the U.S. west coast. The glider collected high-resolution (1 s^-1) observations of temperature (T), salinity, and optode-based dissolved O2 on five transects of the shelf at 44.2°N during August, 2011, a late-summer period of primarily upwelling-favorable conditions. In near-shore surface waters O2 undersaturations indicative of recent upwelling were persistent, while in mid-shelf surface waters O2 supersaturations in excess of 25% were observed, indicative of high rates of biological production. In bottom waters, hypoxia (O2 < 60 µmol/kg) was observed over much of the shelf. We use relationships between T and O2 derived for this region to determine pH and CaCO3 saturation state, to compare to concurrent ship-board measurements, and to evaluate the contribution of multiple stressors (biological/physical) to acidification of shelf waters over the deployment period. (Abstract ID 9538)

Idealized model simulations are carried out examining the effect of cross-shore winds on the mixing of a buoyant river plume system. After several inertial periods of wind forcing the plume is transported offshore and several plume properties (offshore distance, width, depth, density) reach a steady state dependent on estuarine outflow conditions. We used a traditional salt equation and a salinity coordinate analysis to examine this constant plume structure. The wind stress drives a vigorous cross-plume circulation that acts as a straining mechanism, stratifying the offshore side of the plume. This is balanced by the vertical mixing driven by the downstream Ekman velocities. In the salinity coordinate analysis, the freshwater volume in the plume is tracked in both time and salinity space. The structure of the freshwater volume in time and salinity space agrees with a critical Richardson number based mixing ratio, which clearly delineates regions of active mixing from regions where mixing is balanced by the advection of freshwater. This salinity coordinate analysis agrees with the traditional Cartesian coordinate analysis and is useful in examining plume wide processes. (Abstract ID 11954)
Electrochemical Phosphate Monitoring: First Steps to Create an Electrochemical Sensor With an Application in the OMZ Offshore Peru

Developing new sensors for improving our understanding of the coupled biogeochemical cycles constitutes an immense challenge. Electrochemistry promises promising reagentless methods by going further in miniaturization, decreasing the response time and energy requirements and thus increasing our observing capacities in the ocean. We present an electrochemical method for phosphate determination in seawater based on anodic oxidation of molybdenum in seawater in order to create molybdenum phosphate complex amperometrically detected on gold electrode with detection limit of 0.12 µM and an average precision of 2.2 %.

We propose a solution to address the silicate interference issue based on an appropriate ratio proton/molybdate and using an electrochemical cell with an adaptation of specialized membrane technology. We present an application of this method in the OMZ offshore Peru. The results show excellent agreement when compared to colorimetry with an average deviation of 5.1%. This work is a first step to develop an autonomous in situ sensor for electrochemical detection of phosphate in seawater. (Abstract ID 9683)

TRENDS IN THE SURFACE CHLOROPHYLL OF THE CALIFORNIA CURRENT: MERGING DATA FROM MULTIPLE OCEAN COLOR SATELLITES

Standard remote sensing reflectance products from four ocean color sensors (OC3S, SeaWIFS, MODISA, MERIS) and over 10,000 in situ measurements of surface chlorophyll-a (Chl-a) concentration in the California Current were used to create empirical algorithms that are consistent with in situ data as well as between individual sensors. Using these algorithms a merged multi-sensor time series of the surface Chl-a concentration in California Current region was created. The merged Chl-a time series (1996-2011) shows a significant trend of increasing Chl-a off central California and a decreasing Chl-a trend in the central North Pacific gyre. Although this 15-year time series is too short to separate interannual and multidecadal cycles from climate trends, both of the observed trends are consistent with the predicted effects of global warming that is expected to cause weaker vertical nutrient fluxes in the gyre due to stronger stratification of the water column but increased upwelling off central California due to stronger upwelling-favorable winds. (Abstract ID 9714)

THE INTERACTION BETWEEN SHORT OCEAN SWELL AND TSUNAMIS - AN EXPERIMENTAL STUDY

Our objective is to investigate the effect of combined swell - tsunami interaction on the nature of the tsunami – in particular the surface elevation, the runup speed and the near-bottom velocities. Laboratory testing in the Tsunami Wave Basin at Oregon State University has been performed to simulate this interaction, with free surface elevations and near-bottom velocities measured at various locations over a plane sloping beach. Random wave trains with varying initial mean steepness were generated in concert with the tsunami. Preliminary analysis of the data using wavelet transforms reveals that high steepness ocean swell changes the spectral signature of the tsunami, particularly at high frequencies. There is also a significant difference in location of the breakpoint of the tsunami with overriding swell. Further analysis using wavelet coherence will be undertaken in order to untangle the interacting frequencies and shed further light on the nature of the interactions. Numerical modeling of the phenomena (using a nonlinear wave model) will be used to determine the dominant effects. (Abstract ID 11332)

SCALES OF SST VARIABILITY IN GHRRST DATA

The Group for High Resolution Sea Surface Temperature (GHRRST) is an open international science group providing a global user community with Sea Surface Temperature (SST) products derived from satellite observations. A special focus of GHRRST is how spacial and temporal resolution can be optimally preserved in data products derived from merging various sensors of different resolution, and how the trade-off between smoothing and resolution is best communicated to the user. Even if only a single sensor is considered, the spacial and temporal resolution is important in connection with validation and error estimation. This talk will summarize the current status quo and possible ways forward for GHRRST to address the scales of SST variability. (Abstract ID 11662)

CARBON UPTAKE AND RELEASE BY PHYTOPLANKTON COMMUNITIES IN THE AMAZON RIVER PLUME

The Amazon River Plume is a large, highly productive region and is thought to be a carbon sink in the Western Tropical North Atlantic Ocean, based on the riverine nutrient inputs. Phytoplankton utilize large quantities of atmospheric CO2 for photosynthesis, but part of this uptake is known to be released as DOC, affecting the flux into refractory carbon pools.

To determine uptake and excretion of different phytoplankton communities in the area of the Amazon River Plume we measured production and excretion rates by 14C uptake and release in form of DO14C. Rates were normalized to biomass determined by chlorophyll a. We found different production and excretion rates within different communities. A coastal diatom community excreted 92%, a Ceratium dominated community 38%, and a Trichodesmium dominated community 50% of the total carbon uptake of each community. These results show that carbon excretion in the Amazon River Plume depends on the composition of the phytoplankton community. Different areas with different communities in the Amazon River Plume might therefore have different effects on the carbon pools and carbon sequestration. (Abstract ID 11237)

MOELED AND EXPERIMENTAL PREDICTION PREDICTIONS AND CAUTIONS FOR TYPE I AND TYPE II LIQUID CORE WAVEGUIDES
Liquid core waveguides (LCWs) have found use in analyses of liquids for a wide variety of applications. In the oceanographic community, LCWs are primarily used for measurements of chemical concentrations and quantification of colored dissolved organic matter (CDOM). Because LCWs are flexible and conduct light energy efficiently, long optical pathlengths are achievable, providing enhanced sensitivity over standard, shorter cuvettes. By their nature, however, the materials comprising the waveguide interact strongly with propagating light. Due to variations in LCW construction methods, light may not necessarily be confined to travel solely within the liquid sample. As a result, optical absorption measurements may exhibit offsets from absolute values. Currently, two main types of LCWs are employed: a) Type I, which is a tube formed solely from AF 2400; and b) Type II, which is made by coating a quartz tube with AF 2400. We developed optical models to predict the performance of the Type I and Type II waveguides. In this presentation, we discuss the optical performance of the Type I and Type II waveguides, highlighting how light travels throughout the different media comprising the LCWs. We also compare the Type I and Type II results to the performance of bare quartz tube. For the cases where an experimental setup was feasible, we provide a comparison between modeled and experimental data. (Abstract ID 11261)

ROLE OF THE SOUTHERN OCEAN IN SETTING THE ATLANTIC STRATIFICATION AND MERIDIONAL OVERTURNING CIRCULATION
This study examines the importance of the Southern Ocean (SO) stratification in determining the upper cell of the Atlantic meridional overturning circulation (MOC) and stratification. Main results are based on a suite of numerical simulations of the SO-Atlantic System, intended to explore the importance of various dynamical factors. The results demonstrate that the density distribution at the SO-Atlantic boundary is the key factor controlling the Atlantic stratification and MOC, whereas the main importance of the Ekman and eddy (parameterized) exchanges is in setting the SO stratification. Among all aspects of the SO stratification, the position of the deep isopycnals near the western boundary of the Atlantic basin appears to determine the strength of the MOC for given isolocytropic outcrop positions in the North Atlantic. The interplay between the SO stratification and surface density in the North Atlantic is, however, important for MOC. In particular, the steady-state AMOC response to a negative

CHANGES IN RUNOFF FROM THE GREENLAND ICE SHEET RECORDED IN RED CORALLINE ALGAE
The Greenland Ice Sheet (GrIS) contains the largest store of fresh water in the northern hemisphere, equivalent to ~7.4m of eustatic sea level rise, but its impacts on current, past and future sea level, ocean circulation and European climate are poorly understood. Recent estimates of GrIS melt from satellite observations and melt-models indicate increasing melt trends. There are however no runoff data >50y length with which to determine if recent changes are natural oscillations or step changes. Using marine coralline algae we have made the first reconstruction of runoff from a section of the GrIS over several decades. There is a trend to increasing GrIS runoff since the mid 1980s, with the largest annual runoff observed in 2002. There are however no runoff data <50y length with which to determine if recent

EXTREME NITROGEN ENRICHMENT SUPPRESSES N-FIXATION AND DRASTICALLY ENHANCES DENITRIFICATION, BUT NOT ENOUGH
Anthropogenic nutrient inputs are a major concern in estuaries, and can lead to eutrophication and significant impacts on key nutrient cycle processes. Nitrogen (N) cycling is integral to ecosystem function, yet N-fixation and denitrification, which add or remove N, are not well studied, especially in heavily populated Mediterranean areas including edible fishes. Commercially, commercial farming is banned in Fukushima regions and the local fishery industry is severely damaged. We used a microcosm experiment to determine the role of diatoms in commercial importance of fish species, we will conduct a comprehensive survey of activity distribution in seawater, sediment, plankton, benthos, and fish species. Combining other available information, we will discuss radioactivity transfer in pelagic and benthic ecosystems in this region. (Abstract ID 9854)

PROROCENTRUM MINIMUM MAINTAINS HIGH PHOTOSYNTHETIC ELECTRON TRANSPORT UNDER PCO2 STRESS (HIGH pH) BY REDUCING OXYGEN.
Bloom forming species often develop high biomass and conditions of high CO2 concentration, low CO2 concentration, and high pH during the daytime. Such conditions should lead to significant photosynthetic stress and down regulation of photosynthesis to avoid photoinhibition. Contrary to this expectation, cultured Prorocentrum minimum cells maintained high rates of photosynthetic oxygen evolution under high pH and low pCO2. Using membrane inlet mass spectrometry and 18O techniques it was determined that the high rate of gross oxygen evolution under pCO2 stress was balanced by a comparatively high rate of oxygen reduction. F minimum cells exhibited highly variable light-dependent oxygen uptake ranging from essentially no irradiance dependence to a near perfect 1:1 oxygen cycle at all irradiances, depending on pCO2. These results suggest that F minimum has an adaptation that maintains photosynthetic electron transport under bloom conditions to minimize photoinhibition. The high rate of oxygen uptake under low pCO2 may be related to the possession of Form II Rubisco, which has a higher tendency for photosynthetic oxygenase activity than Form I Rubisco. interpreting data. The MBQ partnered with COSEE-West to include an outreach component, instilling in young scientists the importance of communicating research. Students wrote research blogs and created a range of outreach products. COSEE-West ran a concurrent online workshop that connected MBQ scientists to professor, graduate, and undergraduate level to teachers and informal educators, and live webcasted the concluding MBQ Student Research Symposium. Evaluations showed immense value of these experiences for students, scientists, and workshop participants. Students learned “new ways to present my project to different groups of people in a clear way” and 82% rated blogging an A/B grade. One professor commented the online workshop “allowed me to bridge the gap between scientific research and public education,” and 94% of workshop participants learned content they could use in teaching. SHORT-TERM VARIABILITIES IN THE TSUSHIMA/KOREA STRAITS

Short-term variabilities with a time scale from a couple of days to several weeks in the Tsushima/Korea Straits (TKS) are studied using Acoustic Doppler Current Profiler (ADCP) data along the ferry “Camellia” cruise line between Pusan and Hakata. In the cold period (December to April), the variabilities are dominant only in the western channel of the TKS, but spread into the entire TKS in warm period (May to November). The analysis of Empirical Orthogonal Functions (EOF) of the component of the short-term currents normal to the cruise line illuminates three dominant modes. One is a “transport” mode in charge of volume transports with a coherent structure in the entire TKS during a year. The second one is a “vortex” mode with strong locality and seasonality. In the cold period, the vortex mode develops only in the western channel with a dominant time scale of 5-7 days. In the warm period, it develops at the lee of the northern part of the Tsushima Islands and eastern channel with a dominant time scale of 16-17 and 15-16 days, respectively. The third mode is a “baroclinic coastal trapped mode” appearing from July to October near the Korean coast with a dominant time scale of 6-16 days. The transport and baroclinic coastal trapped modes respond to the atmospheric forcing, whereas the vortex mode depends on local geometry, stratification, current shear etc. (Abstract ID 9569)

ON THE INTERANNUAL AND DECADAL VARIABILITY OF THE GULF STREAM

The Gulf Stream is a fast, intense western boundary current system in the Northwest Atlantic. It features energetic mesoscale activity in the form of meanders, rings and eddies with significant variability on seasonal and decadal timescales. We present results from a multi-decadal hindcast simulation (1958-2007) using a high-resolution regional ocean circulation model (ROMS). We quantify the variability in the meso-scale and mean flows and relate it large-scale climate indices. We also evaluate the biases in global climate models in this region and use our model to explore the implications of these biases. (Abstract ID 12538)

INFLUENCE OF ESTUARINE BARRAGE ON SEDIMENT OXYGEN DEMAND AND DENITRIFICATION IN GO-SEONG ESTUARY, SOUTH SEA, KOREA

To investigate the effect of estuarine barrage on organic matter remineralization (sediment oxygen demand, SOD) and denitrification, intact sediment core incubation experiments were performed in small estuarines with (Go-Seong) and without (Gu-Man and Ma-Am). The barrage from August to September, 2011. SOD in the study sites tended to high (3.17 to 37.29 mmol O2mm-2d-1) but the influence of the barrage was not evident. On the other hand, denitrification decreased rapidly with the salinity (denitrification =0.01 to 3.35mmole N2m-2d-1). The degree of decrease was more evident in Gu-Man and Ma-am compared to Go-Seong, especially, the salinity effect was not observed outside of the barrage. Other than the salinity effect, overall denitrification was lower in Go-Seong compared to Gu-Man and Ma-Am probably due to the limited water movement or stagnance. The effects of photosynthesis by microphytobenthos on SOD and denitrification were high in low salinity. (Abstract ID 12738)

PROPAGATION OF THE WIND WAVE WITH STRONG TIDE IN THE WEST COAST OF KOREA

Characteristics of the wind-induced surface wave propagation with strong tide in the west coast of Korea were studied using the buoy and wave radar data set and a simple numerical model. The period selected for this study was on Mar 4-7, 2007. During this period, there was a very high wave record over 9 m of wave height at KyuckYulBee-Do (outside bay), and 6 m at DuckJeuck-Do (inside bay) on Mar. 5, 7:00-8:00 am. Wave-tide interactions were occurred only during the high wave activity period, and time variation of wave height showed tidal period modulation at the inside of bay displaying that high wave energy for the high water and low wave energy for the low water. No tide at outer side bay. The direction of wave propagation was also affected by tide, and peak wave period was increased during the flood tide and decreased during the ebb tide inside of the bay. From diagnostic model runs, the dominant factor to affect the wave height during wave propagating into coastal area was the wave depth change by tide, which was also a key factor to make the tidal modulation of wave height variation, especially at the shallow area. A discussion about how much of wave height can be changed by tidal current, wind or the combined factor, and how can directional wave energy spectrum be deformed, will be included a little bit detail. Keywords: surface wave characteristics, wave-tide interactions, directional wave energy spectrum (Abstract ID 11236)

QUANTITATIVE EVALUATION OF IRON AND NUTRIENTS IN SEA ICE IN THE SOUTHERN SEA OF OKhotsK

To elucidate roles of the sea ice in biogeochemical cycle in the Sea of Okhotsk, the concentrations of nutrients and iron were measured for the sea ice, overlying snow and seawater samples collected in the southwestern region by using clean technique in early February 2010 and 2011. The concentrations of major nutrients in the sea ice, except for NH4-, were lower than those in underlying seawater. Iron in the sea ice was heterogeneously distributed and enriched relative to the underlying seawater. We consider that sea ice melting tends to induce the dilution of the nutrients concentration of surface water, while it might be significant source of iron to surface water in this region. We estimated total iron flux into surface water from melting sea ice as 666±197μmol Fe m-2 event-1 (one seasonal melting). The flux is comparable to reported amount of annual atmospheric iron flux (267-929μmol Fe m-2 yr-1) in the northwestern Pacific. Therefore, our results indicate that sea ice has a significant impact on macro-, micro-nutrient conditions in this region during the melting season. (Abstract ID 10768)

GLIDER FLEET-BASED MULTI-PARAMETER OBSERVATIONS IN THE TROPICAL NORTHEAST ATLANTIC

To study the coupling between physical and biogeochemical parameters, high-spatial resolution, multi-parameter measurements are required. This poses a challenge to ocean observing systems. We present results from a study in the tropical Northeast Atlantic, employing simultaneous observations from 5 gliders. Each glider recorded temperature, salinity, chlorophyll, oxygen and turbidity for the duration of 50 days. A 45 by 45 km wide area was sampled using butterfly-shaped courses, to optimize the area coverage and the intercalibration of the gliders. Our aims included (i) the quantification of the spatial scales of variability in the recorded parameters, (ii) the demonstration of coupling between physical and biogeochemical parameters, and (iii) detectability of deposition of Sahara dust from seawater turbidity. The gliders observed significant variability in form of changes of thermohaline properties, internal waves, and meso-scale features. The scale-dependence of the different parameters is presented. Below the mixed layer, changes in oxygen, and salinity imply spatio-temporal variability of the ratio of North to South Atlantic waters. Pronounced submesocale variability is found, which might be important for the vertical fluxes of nutrients and oxygen. (Abstract ID 11064)

MONITORING THE WESTERN EQUATORIAL PACIFIC SALINITY FRONT USING HIGH-RESOLUTION AQUARIUS SATELLITE MEASUREMENT

Taking the advantage of using global ocean salinity data from Aquarius/SAC-D mission, we are able to obtain the repeated and fully covered salinity maps. The sea surface salinity from satellite measurement has high-resolution both spatially (150km or higher) and temporally (monthly...
to weekly). Western equatorial Pacific is an ideal region to study the salinity variations using the initial measurement of Aquarius. First, in the open ocean, the salinity data is less contaminated by the land. Second, the Aquarius has higher accuracy in salinity retrieval in the tropical region. The reason is that the salinity is more sensitive to the brightness temperature where the sea surface temperature is higher. Third, the existence of a salinity front near the eastern edge of western Pacific warms pool results in large horizontal salinity gradient. Scientifically, analyzing the evolution of western Pacific salinity front could improve our understanding for the formation of barrier layer and the mixed layer heat budget related to the freshwater flux. This presentation analyzes the first look of regional salinity study using the Aquarius satellite salinity measurements. (Abstract ID 12528)

ESCAPE OF TERRESTRIAL ORGANIC PARTICLES DRIVEN BY HYPERPYCNAL FLOW

Tropical cyclones in western Pacific bring torrential rainfall to mountainous islands across Oceania resulting flushing floods, which might play a significant role in the transport of terrestrial organic carbon into deep sea. These processes are particularly effective across the western Pacific. Hyperpycnal delivery occupied 35% of total clastic load yet happening only in 0.7% of time. Here we present organic geochemistry data for a sediment trap deployed at 600 m depth in a submarine canyon off southwestern Taiwan over a period of flood. 13C/TOC and 14C/TOC characteristics of trapped sediments reveal that an enriched organic layer was carried by turbid flow escaping oxidation in shallow water immediately after a flood. The organic-rich layer is recently-fixed organic carbon (90% modern) from terrestrial system. This process should be common in active continental margin where river, narrow shelf and canyon is tightly connected acting as a express gate delivering fresh terrestrial OC into deep sea for burial. (Abstract ID 12534)

IMPROVING THE SUSTAINABILITY OF LONG-TERM UNCABLED HYDRATE OBSERVATORIES: TECHNOLOGIES FOR EFFICIENT DATA RETRIEVAL AND RENEWABLE POWER

Uncabled seafloor observatories are a crucial technology in monitoring local chemical variability induced by hydrate deposits. Often these observatories are deployed for durations of up to a year and are only recovered for data retrieval, refurbishment, and redeployment. Accordingly the primary cost of operation after initial deployment is the infrastructure required for data collection and power supply servicing. Our work aims to improve both the data collection and operational endurance of seafloor moorings by demonstrating two new technologies on a seafloor mooring at the Mississippi Canyon 118 hydrate observatory. The first is an optical modem communication system for easy and efficient data retrieval. In

EFFECTS OF ELEVATED CO2 CONDITIONS ON PARALARVAL LONGFIN SQUID (LOLIGO PEALEII) DEVELOPMENT AND EARLY LIFE

High CO2 emissions since the industrial revolution have reduced ocean pH by 0.1 units, with further reductions predicted for the year 2100. Studies have explored the potential effects of ocean acidification on diverse marine taxa; however, research on cephalopods has been limited. This is surprising due to the central role squid can play in ocean ecosystems. These investigations reared paralarval longfin squid Loligo pealeii from eggs to hatchlings in ambient (~390 ppm) and high (~2200 ppm) CO2 conditions to examine potential effects of ocean acidification on this commercially and biologically important species. Responses were heterogeneous across the experimental trials. Squid raised in high CO2 demonstrated later hatching time (~24 hours) and shorter mantle length at hatching (t=2.381, p=0.018, df=158) in trial 1 but not trial 2. Aragonite statoliths, used for balance and acceleration, were significantly shorter and more porous in high CO2 reared larvae (t=3.086, p<0.007, df=16). While clear differences were found between ambient and high CO2 animals, biological impacts are uncertain. Results suggest concern for the need for further research regarding ocean acidification impacts on squid. (Abstract ID 10572)

OCEANOGRAPHY MAGAZINE AS A VEHICLE FOR COMMUNICATION IN THE OCEAN SCIENCES

The Oceanography Society (TOS) was founded in 1988 with a primary mission to disseminate knowledge of oceanography and its application through research and education, to promote communication among oceanographers, and to provide a constituency for consensus-building across all the disciplines of the field. The principal way that TOS accomplishes this mission is through quarterly print and online (open access) publication of OCEANOGRAPHY. Through peer-reviewed articles written in a less-technical style than most other journals, and insistence on high-quality color graphics, major programs use OCEANOGRAPHY to communicate their accomplishments to a broader audience, including academic oceanographers from all disciplines, program managers, and policy makers. OCEANOGRAPHY also advances cross-disciplinary communication through thematic special issues, for example, the June 2011 volume on sea level. Occasional publication of supplements to the magazine, such as "Scientifically Speaking" and "Education and Public Outreach: A Guide for Scientists" are additional ways that TOS contributes to promoting excellence in communication within and outside of the ocean sciences community. POP/DART: AN ENSEMBLE DATA ASSIMILATION SYSTEM FOR THE OCEAN COMPONENT OF CESM

At the National Center for Atmospheric Research, a 48-member ensemble adjustment Kalman filter (EaKf) is being used to assimilate daily subsurface temperature and salinity data into the POP 1x1° global ocean model. The new ocean assimilation system dovetails with an existing EaKf system for CAM, the atmospheric component of CESM: each ensemble member of the ocean model is forced at the air-sea interface by a unique sample of the atmospheric state as it was implemented for that multidecadal climate prediction effort. We have a continuous analysis from Jan 1, 1998 to Dec 31, 2005, which serves both as initial conditions for the decadal ocean assimilation system for CAM, the atmospheric component of CESM. The development of an ocean analysis at NCAR was originally outside of the ocean sciences community. (Abstract ID 231)

LOW OXYGEN EDDIES IN THE OPEN NORTH ATLANTIC OCEAN

We report on sporadic events of extremely low oxygen values at the northern rim of the North Atlantic Oxygen Minimum zone, based on observations from multiple platforms (glider, float, mooring). The low oxygen conditions occur just below the mixed layer and are associated with mesoscale eddies. By utilizing satellite altimeter data to reconstruct the eddies’ pathways we find that they have been generated by the instability of the eastern boundary current in the high-productive Mauritian upwelling region, off West Africa. Within the eddies, the degree of oxygen depletion is consistent with consumption rates found in the upwelling region. The efficiency of oxygen consumption seems to be influenced by eddy dynamics and simple, conceptual models for consumption scenarios for different ’types’ of eddies (cycloic, anti-cycloic, mode water) are presented. The implications of these extreme low oxygen conditions for the North Atlantic OMZ are discussed. (Abstract ID 11175)

IMPACT OF ICE COVER ON WIND-FORCED EXCHANGE IN THE ALASKAN BEAUFORT SEA

The Alaskan Beaufort shelf is fed by Pacific water emanating from Bering Strait, and is strongly wind-forced in fall and winter due to the passage of synoptic storms. The pack-ice tends to be fast on the inner shelf and more mobile farther offshore, modulating the water column response to such storms. Here we use data from the first-ever mooring array extending from the inner shelf to the continental slope to investigate the cross-shelf exchange and water column properties during two wind events characterized by differing ice conditions. In the first event (early December 2008) the ice was mobile everywhere, while much of the shelf was covered by fast ice during the second event (early February 2009). The salinity, temperature and velocity response strongly depended on the ice-free shelf region near the shelfbreak where the ice remained mobile throughout the event. The connectivity between the inner and outer shelves and resulting cross-shelf transport is assessed in each case. (Abstract ID 9941)

PREDICTING WAVE-CURRENT INTERACTIONS AT THE MOUTH OF THE COLUMBIA RIVER, OR

The wave conditions at the mouth of the Columbia River (MCR) are modeled using the spectral wave propagation model SWAN, and a forecast is developed as a navigational safety tool. The waves at the entrance to the MCR are strongly affected by the tidal currents as strong ebb flows can significantly steepen the waves and induce localized breaking. Included in the model are offshore wave conditions obtained from a 30 arc-second resolution WaveWatch3 forecast and current fields obtained from a river circulation forecast. Comparing the model results to the Catstop Spt buoy, located in 25 m water depth just south of the inlet, shows the forecast is skillful at predicting the general wave height trends. For a 6-week period in Summer 2011 when wave heights ranged between 1.0 and 3.1 m, the forecast had an rms error of 29 cm. Results also show that the influence of the tidal current is limited to the area within the 25 m contour line, but within this area, the wave heights during ebb tide can be as much as 2.5 times the slack tide wave height. ONTOGENETIC PROPULSIVE TRANSITIONS FROM VISCUS TO INERTIAL FLOW REGIMES

Among marine organisms, the influence of flow regimes on swimming strategies is largely unknown. As an approach to examine this issue, we quantified how transitions from viscous to inertially dominated flow regimes, which commonly occur during the development of marine animals, relate to changes in swimming strategies. We used the hydromedusa Sarsia tubulosa as a model organism for this investigation because its morphology and propulsive actuation mechanism are radially symmetric. This feature allows for determination of three-dimensional fluid quantities from two-dimensional flow measurement techniques. Digital particle image velocimetry was used to quantify the flow fields created by free-swimming hydromedusae and calculate the kinetic energy, circulation, and impulse generated by their swimming pulses at different life stages. Swimming strategies were evaluated by quantifying the relationship between impulse production and hydrodynamic swimming efficiency. The use of impulse theory enables us to generalize our findings to the swimming strategies of other aquatic animals that swim in similar flow regimes. (Abstract ID 11739)

THE VARIATION OF THE NORTH PACIFIC TROPICAL WATERS IN ITS FORMATION REGION, 2003−10

The monthly mean gridded temperature and salinity data based on Argo profiling float observations in 2003−10 were analyzed to investigate the variation of the North Pacific Tropical Water in its formation region. The formation region, namely the sea surface salinity maximum at 20°−30°N, 160°−140°W, is narrow in the middle due to the persistent existence of a local salinity minimum near 20ºN, 170ºW, and is separated into eastern and western parts. The characteristics of the mixed layer salinity variation are different between the western and eastern areas. Interannual variations are dominant in the western area, while seasonal variations are dominant in the eastern area. The estimation of mixed layer salinity budget shows that evaporation and precipitation dominate other factors in both areas, except that entrainment becomes important in fall to winter in the eastern area. The mixed layer salinity in both areas has increased since 2008, at a higher rate in the western area. This is likely to be caused by a decrease in the Southern Annular Mode index. (Abstract ID 10836)

AN INVESTIGATION OF MODIFIED CIRCUMPOLAR DEEP WATER THROUGH AUTONOMOUS GLIDER MEASUREMENTS IN THE ROSS SEA

The Ross Sea's high biological productivity and variable conditions make it an important component in the global marine carbon cycle. Autonomous sea gliders deployed in the Ross Sea provide a means for resolving highly variable phenomena, such as Modified Circumpolar Deep Water (MCDW) intrusions onto the continental shelf. These gliders more easily assess the temporal and spatial extent of MCDW intrusions in the Ross Sea than traditional measurement platforms, e.g., cruise samples, CTD casts, and satellite observations. Two gliders deployed within the Ross Sea in late November 2011 made over 1590 dives and collected data (salinity, temperature, fluorescence and oxygen) for approximately two months. These temperature and oxygen data can locate intrusions of MCDW in the Ross Sea. Preliminary analyses of these data indicate a positive correlation in space between the presence of MCDW intrusions and high fluorescence, suggesting a biological effect on summer plankton blooms. Further comparisons to contemporaneous cruise and satellite data highlight the capacity of gliders for resolving correlations between fluorescence and MCDW and providing insights into the mechanisms of the relationship. SEASONAL VARIABILITY OF EXCHANGE CIRCULATION AND HYDROGRAPHY IN A FJORD ESTUARY: A NUMERICAL MODEL STUDY

A three-dimensional hydrodynamic model is used to study seasonal variability of circulation and hydrography in Hood Canal, Washington, an estuarine fjord that develops seasonally hypoxic conditions. The model is validated with data from Year 2006, and is shown to be capable of quantitatively realistic simulation of hydrographic variability. Sensitivity experiments show the largest causal factor for seasonal variability to be that of salinity at the mouth of the fjord. Variability of fresh water input from the watershed also causes significant, but secondary, changes; local wind stress has little effect over a seasonal timescale. Further experiments, in which one forcing parameter is abruptly altered while others are kept constant, show that outflow changes are significant but also that upwelling feedbacks can influence the rate of water exchange.

AN ANALYSIS OF COPEPOD FEEDING USING FLOWCAM

Two copepod species dominate the zooplankton in the Upper San Francisco Estuary during summer, Pseudodiaptomus forbesi and Limnomena tetraspis. These copepods are an important food source for many fish species, including the endangered Delta Smelt. Little is known about their feeding and in particular whether they compete for food. This study aimed to identify the types of prey that these copepod species consume and quantify their feeding rate. Copepods were collected from the Upper San Francisco Estuary and incubated for 24 hours in surface water from the collection site, which contains their natural prey. Microplankton from incubation bottles with and without copepods are counted, measured, and grouped.
into broad taxonomic categories (cilates, flagellates, diatoms, etc.) using a FlowCAM imaging particle analyzer. The FlowCAM combines features of a flow cytometer, including fluorescence trigger, with an optical system similar to a microscope that captures digital images of particles. The FlowCAM software takes automated measurements of the particle images which were used to help categorize different types of plankton and estimate their biomass. This project demonstrates the utility of this instrument for rapid, accurate measurements of feeding rate. (Abstract ID 9894)

PROGRESS OF NOAA’S CLIMATE DATA RECORD PROGRAM

The Climate Data Record (CDR) Program is entering its 3rd year of funded activities at NOAA’s National Climatic Data Center (NCDC). The CDR Program has already promoted and is maintaining 8 global satellite-based CDRs in an operational state within NOAA. The Program has conducted two competitive award cycles which has funded 18 awards totaling over $13,000,000. Several are ocean Thematic CDRs while others are Fundamental CDRs upon which ocean products are based. Standards for the transition of research-grade code to an operational environment, data set formatting and documentation, processing transparency, and the quantification of the CDR’s maturity have been developed by the Program through coordination with partners in the scientific community. The Program is exploring the application of these standards to many CDRs not captured through the competitive awards program to secure them and thus facilitate assessments, adaptation, and mitigation of climate change. Future directions include definition of maintenance profiles to ensure transition to a fully operational state for each CDR and the application of the operational CDR algorithms to new data streams to aid in climate monitoring activities. STOCHASTIC SUPERRESOLUTION OF THE UPPER OCEAN FLOW FIELD ESTIMATED FROM SATELLITE ALTIMETRY

Attempts to monitor eddy transports in the ocean are strongly limited by the sparseness of available observations, the strong nonlinearity of the underlying dynamics, and the fact that eddy transport is particularly sensitive to unresolved submesoscale dynamics. In this study, a suite of stochastic data assimilation methods for estimating eddy transport are tested in idealized simulations of quasigeostrophic turbulence at high and low latitudes under a range of observation scenarios. A novel feature of these strategies is the use of computationally inexpensive stochastic forecast models with model parameters that can be learned adaptively from the observations themselves. We demonstrate the feasibility of a simple technique for deriving “stochastically superresolved” velocity fields with a nominal resolution increase of a factor of two or more. This is achieved by extracting high-wavenumber information that has been aliased into the low wavenumber band and combining it with a model for the unresolved kinetic energy spectrum. We show that estimates of the time-mean poleward eddy heat transport estimated in this way are significantly closer to the true value when compared with standard estimates based upon optimal interpolation. Implications for measuring poleward eddy heat transport using current and next-generation altimeters are discussed. (Abstract ID 10737)

BENTHIC POPULATION DYNAMICS AND DIVERSITY IN THE WARMING CHUKCHI SEA

The Chukchi Sea is currently exposed to increasing temperatures and experiencing major reductions in seasonal sea ice cover. Changes in the sea ice extent, thickness and duration are critical for influencing annual primary production of ice algae and phytoplankton and therefore for benthic populations, ecosystem function, trophic dynamics and organic carbon cycling. The main aim of this study was to examine structure, function and diversity of benthic infaunal organisms in the high biomass/diversity “hot spot” areas of the Chukchi Sea with a goal of assessing biological vulnerability to increasing temperature and sea ice reduction as well as implications for marine food web changes. A collection of approximately 100 van Veen grabs was taken (35 – 130 m depth) to assess benthic diversity, abundance and biomass at the same stations in both 2010 and 2011. The results are presented in relation with physical and chemical data and compared to selected time series results from the past 30 years. This study is a part of the Distributed Biological Observatory (DFO) program and represents a continuation of benthic time series collected since the 1980s. (Abstract ID 9865)

OPTICAL ESTIMATION OF BREAKING WAVE INDUCED DISSIPATION

Depth-induced wave dissipation is directly related to radiation stress gradients which drive circulation within the surf zone. Optical remote sensing methods are able to detect this temporal and spatial distribution of energy due to the increased bubble production and the associated increase in reflected light. The goal of the present research is to understand how these changes in radiance and depth induced wave dissipation are related. Using the Battjes & Janssen (1978) time averaged dissipation equation as a framework, it is proposed that the dissipation is related to the radiance through the fraction of breaking. A relative radiance quantity (L = L_LT, Target) is derived, which relates the local radiance to the radiance produced from a target Lambertian surface. Remote sensing derived dissipation estimates are then compared with one-minute time averages of in situ dissipation collected by a fixed Aquadopp over six days within the surf zone. Both long time scale variations associated with tide level changes and sub-minute variations associated with wave groups are investigated. (Abstract ID 9847)

THE ESTABLISHMENT OF AUTONOMOUS SHIP BASED OCEAN COLOR OBSERVATIONS ON AUSTRALIAN RESEARCH VESSELS

As part of Australia’s Integrated Marine Observing System, a “Dynamic above water radiation and irradiance collector” (DALEC) was commissioned in August 2011 on the RV Southern Surveyor to provide a continuous stream of hyperspectral information from Australian waters. The DALEC is a radiometrically calibrated spectroradiometer which measures above-water-leaving radiation, sky radiation and downwelling irradiance. Designed for autonomous ship deployment, the DALEC incorporates a passive 2 axis gimbal, solar azimuth tracking, embedded GPS, compass and accelerometers for recording sensor geometry. Dynamic integration time selection ensures optimum signal to noise ratios throughout deployment. The deployment system on the vessel’s forecastle allows the instrument height to be adjusted for safe cleaning and servicing, whilst reducing the effect of bow waves and ship superstructure on the measurements. Radiometric data streams from the DALEC are collected in real-time and recorded over the ship’s local area network, allowing for future integration into onboard data management systems. Preliminary results will be presented from the DALEC test deployments carried out in the Southern Ocean and Indian Ocean. (Abstract ID 11156)

SIMULATING THE ESTUARY TURBIDITY MAXIMUM WITH AN ADAPTIVE MESH CFD MODEL (GERRIS)

We are studying the impact of material properties (e.g., density and viscosity), channel morphology, and boundary conditions on the estuary turbidity maximum (ETM) with a computational fluid dynamics (CFD) code that uses adaptive mesh refinement (Gerris). Our analysis of the lock-exchange problem suggests that dimensionless simulations must be carefully defined because of the changing nature of the flows. We are completing tests that evaluate the relative contribution of buoyancy–driven and tidal currents to mixing in the ETM. This includes a generation of turbulence at the bed using direct numerical simulation (DNS) of flow over bed forms for comparison to turbulence parameterizations. The large change in water depth over a tidal cycle is also a factor because the straightforward application of the 2DV CFD model with a rigid surface cannot be justified for very long. This factor is being examined using the VOF module. The VOF approach has allowed the simulation of tidal flow for water depths ranging from 0.5 to 2.5 m. We are further investigating a hybrid method using VOF and CFD calculations of flow in the ETM. (Abstract ID 11559)

NORTH ATLANTIC OCEAN CONTROL ON SURFACE HEAT FLUX AT MULTIDECADAL TIMESCALES

Nearly 50 years ago Bjerknes suggested that the character of large-scale air-sea interaction over the mid-latitude North Atlantic Ocean differs with timescales: the atmosphere drives directly most short-term – interannual – sea surface temperature (SST) variability; while the ocean contributes significantly to long-term – multidecadal – SST and atmospheric changes. Although the conjecture for short timescales is well accepted, understanding Atlantic multidecadal SST variability (AMV) remains a challenge, due to limited ocean observations. Here we construct long-term (1980-2010) time series of surface turbulent fluxes in the North Atlantic using exclusively Voluntary Observing Ship (VOS) data. The reconstruction makes extensive use of probability distributions of surface fluxes and censored sample theory for minimization and homogenization of time dependent sampling errors. Using these data we provide the first compelling observational evidence that in the mid-latitude North Atlantic and at timescales longer than 10 years, surface turbulent heat fluxes are driven by the ocean and force the atmosphere, while at shorter timescales the converse is true. This result is strongest in boreal winter, but is found in all seasons. These results are also contrasted against those of ocean and coupled model simulations. Our findings indicate that the predictability of mid-latitude North Atlantic ocean could extend beyond the ocean to the climate of surrounding continents. (Abstract ID 11511)

COMPARATIVE ORGANIC GEOCHEMISTRY OF SINKING PARTICLES COLLECTED USING NET TRAPS DEPLOYED IN Oligotrophic, Coastal and fjord SETTINGS

Sediment net traps were deployed for short periods (1-3 days) in a variety of world ocean environments. Samples from the Azorean Sea (2007), Glacier Bay (2008), Clayquot Sound (2006-present), the Washington Margin (2010), HOTS (2010) and BATS (2010) have been evaluated for their amino acid, lignan, phthalate, carbonate, opal and lithogenic mineral compositions. These samples range from well oxygenated to fully anoxic. The goal is to evaluate organic-mineral coupling and the impact of different mineral sources and oxygen tensions on organic matter reactivity and flux. We observed, as has been seen frequently in other suboxic zones, a relatively less attenuated flux through the suboxic waters than is commonly observed in oxic waters. As expected, allochthonous compounds such as lignin (terrestrial organic matter) and phthalate esters (plasticizer) have concentrations and compositions that are strongly correlated with proximity to land. Conversely, autochthonous materials such as amino acids are strongly correlated with local primary production. An in situ incubation system was used at several locations to correlate attenuation rates estimated from trap fluxes to organic matter degradation rates measured in situ. (Abstract ID 12524)

BUILDING A HIGH-POWER AND HIGH-BANDWIDTH CABLED OBSERVATORY ON AN ACTIVE UNDERWATER VOLCANO AXIAL SEAMOUNT

Axial Seamount is the most active volcano on the Juan de Fuca Ridge, erupting in 1998 and 2011. It is both seismically and hydrothermally active, and hosts diverse biological communities. It is a long-term NOAA-PMEL observatory where long-term co-registered fluid chemistry-temperature-microbiological measurements have been made that begin to quantify the microbial evolution at the decade scale of seafloor eruption cycles. Because of these characteristics, Axial was chosen as the US first cabled observatory at a submarine volcano. This 5-year construction and 25-year operational project is part of the NSF’s Ocean Observatories Initiative. The OOI-RSN provides high power (8 kW) and bandwidth (10 Gbps) connectivity to a state-of-the-art full (3 kW; 1 Gbps) water column mooring (3000 m water depth) with two instrumented profilers at the base of the volcano and an array of seafloor sensors in the caldera including a thermistor, high definition camera, an array of seismometers, and fluid-DNA samplers installed in 2013-2014. In concert, this infrastructure will provide unprecedented real-time data flow to a global user community and response capabilities to seismic-eruptive-megaphane events. (Abstract ID 12507)

BACTERIAL COMMUNITY COMPOSITION AND HYDROLYTIC ACTIVITY IN ARCTIC NEPHELOID LAYERS

Nepheloid layers (NL) constitute an important mechanism for cross-shelf transport of particulate-organic carbon (POC) in the Arctic and other oceans. Despite the potential for microbial attenuation of POC during transport, evaluations of microbial communities in NL are rare. Bacterial community composition (BCC) and extracellular enzyme activities (EEA) of free-living and particle-associated microbes were examined in NL transiting the Mackenzie Shelf region of the Beaufort Sea in winter and spring, 2008. BCC in spring NL was similar to BCC in chlorophyll (Chl) maxima, with free-living communities being the most similar and BCC associated with sinking and suspended particle fractions showing greater differences from shallower counterparts. Bacterial communities in NL differed seasonally, possibly due to differences in organic matter source and availability. EEA in nepheloid layers was related to measures of organic lability, especially particulate nitrogen. Contrary to expectation, cell-specific EEA in deeper NL was not significantly lower than that in Chl maxima, indicating that microbial hydrolysis continues in NL at a level that can reduce the amount of POC eventually exported offshore into deeper regions of the ice-covered Beaufort Sea. TEMPORAL VARIABILITY OF VERTICAL HEAT FLUX FROM THE MAIN ENDEAVOUR FIELD, JUAN DE FUCA RIDGE

Hydrothermal vents, and the fluids that emanate from them, are the seafloor expression of a magma body that is undergoing convective cooling. The magnitude of heat that can be extracted through these convective processes is dependent on many factors of the subseafloor geosystem, i.e. heat content of the magma body, thickness of the conductive boundary layer, and the permeability of the fluid network. Changes to this geosystem are reflected in the vertical flux of the buoyant plume. We report on the first comparable repeat measurements of vertical heat flux from a hydrothermal vent system, the Main Endeavour Field (MEF) on the Endeavour Segment. Autonomous underwater vehicle surveys of heat flux from MEF measured a decrease of ~50% between samplings (2000: 538 ± 57 mW → 2004: 278 ± 28 mW). In addition to an estimate of the heat flux from the whole field, we estimate the heat flux on the cluster, or structure, scale as well. Relative differences on the cluster scale are likely indicative of inflation rates in the underlying axial magma chamber. (Abstract ID 11900)

CONTRIBUTIONS TO EIGHTEEN DEGREE WATER INTERANNUAL VOLUME ANOMALIES

The processes contributing to the formation and dissipation of Subtropical Mode Water in the North Atlantic, or Eighteen Degree Water (EDW), are the subject of the CLivar MOD Water
Dynamics Experiment (CLIMODE). To complement the field program with a perspective of interannual-to-decadal variability, we used a simple box model to hindcast observed EDW volume anomalies in two regions: the formation region and an adjacent region where EDW does not outcrop. Formation by air-sea fluxes was estimated explicitly using OAFlux fields for 1985-2007. The relative contributions of Ekman and geostrophic advection and lateral mixing are examined by using proxy variables derived from winds, SST, hydrography and altimeter. The importance of each process is evaluated by its contribution to reproducing observed EDW volume anomalies in the two regions. Volume loss in the formation region is apportioned between subduction (35%) and mixing (65%). Air-sea heat fluxes account for more than 25% of the interannual volume variance. Other important contributors are lateral mixing parameterized by the meandering Gulf Stream and anomalous oceanic circulation. (Abstract ID 10508)

Kelly, S. M., University of Western Australia, Crawley, Australia, samuel.kelly@uwa.edu.au

COUPLING EQUATIONS FOR LINEAR TIDES

Internal tides are generated, reflected, scattered, and dissipated along the continental margins. The relative vigor of these processes determines the strength and location of internal-tide currents and tidally-driven mixing. By approximating continental slopes as two-dimensional, we have developed a new and efficient analytical method for quantifying the interaction of surface and internal tides in regions of arbitrary stratification and topography. Our method decomposes topography and stratification into discrete sets of regions that are locally flat and have horizontally-uniform stratification. We then match the amplitudes and phases of “flat-bottom” vertical modes in the adjoining regions at each discontinuity. The matching conditions result in a set of coupling equations for linear tides (CEL), which are solvable via a single matrix inversion. We show that solutions to CELT agree with analytical and numerical solutions over smooth topography. We then apply CELT at several locations in the ocean. Preliminary results suggest that we can quantitatively estimate (i) directional energy fluxes in 2D partially-standing waves, (ii) two-way energy transfer between the surface and internal tides, and (iii) the efficiency of internal-tide scattering to high wavenumbers. These analyses provide new perspective on the cascade of tidal energy from large- to small-scale motions. (Abstract ID 9497)

ORBITAL FORCING CONTROLS ON ANTRCTIC POLAR FRONT MIGRATION AND DEEP CIRCULATION CHANGE OVER THE PAST MILLION YEARS

The paleoceanographic record of Southern Ocean variability has the potential to provide insights into the key mechanisms and thresholds of change in ocean circulation that have strongly influenced overall ocean system behaviour. Ocean deep circulation is known to undergo radical restructurung during glacial-interglacial cycles and this has been attributed to the role of migration of the mid-latitude westerlies in driving changes in deep-ocean ventilation and hence atmospheric CO2 concentration. During the longer time scale of the mid-Pleistocene transition there is evidence that insolation-forced changes drove deep ocean circulation into a sustained “interim state” during which there was a reduction in the strength of deep circulation and incomplete ventilation of the deep ocean even during interglacial periods. Using the history of migration of the Antarctic Polar Front we provide a synthesis of the sequence of events that tracked these systematic changes in earth system behaviour in relation to external forcing and review consequences for the carbon cycle. We also give the results of preliminary intermediate complexity modelling to provide insights into some of these events and processes. (Abstract ID 11178)

WHAT DRIVES CHAOS IN MODELLED PHYTOPLANKTON COMMUNITIES?

The vast number of phytoplankton species in the ocean is often explained in terms of a chaotic response to the environment. This response is investigated here using two similar, but not identical, ecosystem models by Huisinga and Weissing (1999 HW) and Follows et al. (2007) for a well mixed box. The existence of chaos is verified by diagnosing the maximal Lyapunov Exponent and a 0-1 test for chaos, based on model integrations for a long-term equilibrium. A contrasting response has been observed; the HW model exhibits a variety of responses: competitive exclusion, oscillations and chaos. The Follows model does not show chaotic behaviour: The different response turns out to be due to HW including a parameterized nutrient supply rate depending on the background nutrient conditions, which is not included in the Follows model. Omitting this feedback removes the chaotic response in the HW model. We discuss the relevance of model resource boundary conditions to the real environment, and the consequences for chaotic behaviour in real phytoplankton communities. (Abstract ID 10205)

A VERTICAL MODEL APPROACH TO LONG BAROCLINIC ROSSBY WAVES OVER TOPOGRAPHY

The dynamics of long baroclinic Rossby waves over large topography is investigated using a new theory, idealized modeled, and GCM results. The theory was developed by decomposing the conservation laws of mass and momentum into standard vertical modal components in the presence of steep topography. Each vertical mode Rossby wave propagates along contours of (Coriolis parameter) / (corresponding equivalent depth), modified by topographic interactions between vertical modes that alter the phase speed and vertical structure. The normalized gradient of (Coriolis parameter) / (water depth) provides the magnitude of topographic effects relative to planetary beta effects, neglecting wave directionality. The theory was applied to zonally-varying, meridionally-periodic one-dimensional modeling with realistic zonal bathymetry and Ekman forcing. The results suggest that the barotropic and first baroclinic Rossby waves interact strongly and tend to travel together, with the phase speed close to that of the first mode. This result is compared to more realistic ocean GCM results, which suggest the existence of additional factors that cause strong interactions of the first and second baroclinic modes. (Abstract ID 11077)

ANTHROPOGENIC RADIONUCLIDES IN THE ATLANTIC: GEOTRACES SECTIONS A11 AND A02

We are focused on determining the total concentrations of the anthropogenic radionuclides 239Pu, 240Pu, 237Np, and 137Cs in depth profiles from 2010 Atlantic GEOTRACES sections. Data from the equatorial region (A11) compared to GEOSECS data indicate water column inventories of 137Cs have increased over the last 40 years, whereas those of Pu are variable. By comparison, Pu and 237Np water column inventories are similar to regional soil core inventories, whereas 137Cs inventories are significantly higher, further suggesting continued supply of 137Cs to the open ocean. Water column Pu/237Np inventory ratios are indicative of regional fallout (~0.18). Deviations of the water column 237Np/240Pu inventory ratio from the average global fallout value (~0.08) can be used to estimate Pu-particulate fluxes, which are comparable to sediment trap data and may be used to assess scavenging at different locations along the cruise track. Data from mid and high latitude regions (A02) will be compared to GEOSECS data; inventories and ratios will be used to identify additional contaminant sources, as water mass tracers, and to elucidate important processes such as scavenging and remineralization. Jenneke Westerink, , University of Notre Dame, , Mark Hope, , University of Notre Dame, Urbah Gravios, , University of Florida, Brian Zachry, , AIR Worldwide, , FORERUNNER SURGE AND SHELF WAVES IN ADVANCE OF TROPICAL CYCLONES

Large increases in coastal water levels, called forerunners, have been observed well before
tropical cyclone landfall when winds are not strong and may even be blowing offshore. We present observational and computational results from Hurricane Ike showing the geostrophic nature of its forerunner, the nearly 2m shelf wave that travelled in advance of the storm, and the large water level increase in inland bays attributable to the forerunner. Simple analytical models show the surprising result that the time required to generate the currents driving a forerunner decreases with increasing wind speed, thus not only will forerunners for strong storms be more severe, they are also more likely to reach their maximum possible size. CURRENT-METER PERFORMANCE COMPARISON IN HIGH CURRENT CONDITIONS IN DRAKE PASSAGE

Previous current-meter intercomparisons suggest that Aanderaa RCM11s are biased low in the speed range 0-35 cm s\(^{-1}\). A short near-bottom (4000 m depth) mooring deployed in Drake Passage revisits this bias. The mooring consisted of seven current meters representing four models (two VMCMs, two RCM11s, two Aanderaa SEAGUARDS, and a Northek Aquadopp). Two high-current events occurred (>35 cm s\(^{-1}\)). All current-speed measurements agreed within about 5%. The VMCMs, chosen as the reference, were found to measure the median current-speed. The RCM11 and SEAGUARD current speeds did not differ significantly from 1:1 relationship with the VMCMs, and all three types tended to agree best at higher speeds (35-70 cm s\(^{-1}\)). The Aquadopp current speeds were about 5% higher than the VMCMs but because of a short record this comparison only extended over the range 0-40 cm s\(^{-1}\). (Abstract ID 9471)

COSEE-WEST OCEAN OBSERVING INSTITUTE: USING ONLINE DATA IN THE CLASSROOM

During a five-day COSEE-West Summer Institute K-12 teachers learned about a variety of Ocean Observing systems (OOS), such as buoys, gliders, ROVs, and satellites, and engaged in field sampling and hands-on activities for teaching about ocean observing. The workshop was designed to connect teachers with scientists who use OOS in their research, and provide resources and instruction for using OOS data and graphics in the classroom. Participants visited five different research institutions where they had opportunities to use CTDs and other instruments, build and operate ROVs, view a satellite control room, and participate in model classroom activities. Teachers explored ideas with each other about how to teach using online data and were required to develop lesson plans incorporating OOS. Evaluations from the workshop were very positive. 97% of participants agreed or strongly agreed the workshop enhanced their professional expertise, 95% intend to implement material in the classroom, and 97% felt workshop activities would be effective for students’ learning. One participant wrote, “I will use so much of what I learned in my classroom to help enrich learning for my students.” (Abstract ID 12220)

TRAJECTORIES IN DIATOM SIZE STRUCTURE IN RESPONSE TO RECENT WARMING

The size structure of phytoplankton communities influences food web structure and elemental cycling. There is evidence that climate warming causes a decrease in the average cell size of phytoplankton communities. For example there has been a decrease in the average size of the dominant fossilized diatom community in the ocean over the Cenozoic and a decrease in the average size of diatoms from lake Tahoe over the last decades. Here we show that in a sub-arctic lake that the average size of diatoms is relatively stable over the last two hundred years. The stability in the average size of the diatom community is maintained by a balance between an increase in abundance of small centric species which are becoming smaller and an increase in cell volume in the four numerically dominant larger-sized Aulacoseira species. We propose that over decadal to millennial timescales the trajectories in diatom community size structure in response to climate change may differ between high and lower latitude systems due differences in the timing and types of changes in the associated physical and chemical conditions. MODELING TURBULENCE AND SEDIMENT TRANSPORT NEAR SEVERAL SCOUR HOLES WITHIN A TIDAL INLET

Indian River Inlet is the only waterway connecting two Delaware inlets deep to Atlantic Ocean. The US Army Corps of Engineers constructed twin jetties in late 1950’s to prevent the inlet infilling. Following stabilization, significant channel-bed erosion has occurred. Tidal velocities can exceed 2.5 m s\(^{-1}\) in the constricted channel with Reynolds numbers exceeding 10\(^7\) during peak flood and ebb tide velocities. Sediment transport processes have caused scour holes over 30 m deep (compared to roughly 10 m background depth) to form on the landward and seaward sides of in-water bridge piers that support a major coastal highway. A multilayer non-hydrostatic numerical model (NHWAVE) including turbulence and sediment transport modules is used to investigate the evolution pattern of scour holes inside the channel. Predicted bed shear stresses are used with a sediment pickup function to evaluate sediment suspension. Suspended sediments are then traced by an advection-diffusion equation. Finally, estimated channel-bed evolution is compared with known morphologic variability. (Abstract ID 10353)

CIRCULATION OF THE CORAL SEA FROM MAPPED ARGO TRAJECTORIES

Coral Sea circulation is described using QC-ed, objectively-edged Argo parking-depth trajectories that reference climatological geostrophic shears, defining absolute velocity at all levels above 2000m. Transports are diagnosed in the context of the linear Island Rule, and property advection is compared to along isopycnal velocity fields; several discrepancies are noted. Three currents: the Coral Sea; the shallow North Vanuatu Jet (NVJ; 9 Sv) and the much thicker and narrower North (NCL126 Sv) and South (SCJ; 85 Sv) Caledonian Jets. These last two have maxima near 300m, and significant magnitude below 1000m. Surprisingly, much of the NVJ turns north into the Solomon Sea before reaching the western boundary. The East Australian Current begins as a shallow southward flow near 15°S, marked by low-oxygen water from the NVJ. Conversely, northward flow begins as far south as 26°S below 1000m, fed by high-salinity, high-oxygen water from the SCJ and especially the NCJ. Narrow property tongues trace the boundary current around the Gulf of Papua, showing two separate connections from the South Pacific gyre to the Solomon Sea: one via the western boundary; the other in the interior. POTENTIAL OF GEOSTATIONARY OCEAN COLOR OBSERVATIONS FOR THE RETRIEVAL OF THE DIEL VARIABILITY OF OCEANIC OPTICAL PROPERTIES

Numerous studies were performed since the 1990s on the diel variability of optical properties in various oceanic regimes. It is a well established phenomenon, which is observed in situ and can be replicated in the laboratory. Previous works essentially focused on the particulate beam attenuation coefficient, \(c_p\), with very few experiments concerning the particulate backscattering coefficient, \(b_p\), and the apparent optical properties (AOPs). The latter are the ones that contribute to the satellite signal that can be recorded with ocean color sensors. This variability has been investigated using in situ measurements of optical properties performed at high frequency at a fixed mooring site in the Mediterranean Sea (BOUSSOLE site). We observed a diec cycle in \(c_p\) and \(b_p\), with minima generally near sunset and maxima near sunrise. The transfer of this variability to the AOPs, such as the reflectance, has been also investigated. This is a preliminary step to evaluate the possibility to retrieve the diec cycle of optical properties from ocean color observations taken from the geostationary orbit (including uncertainties introduced by the atmospheric correction process). THE IMPACT OF THE INDONESIAN THROUGHFLOW AND TIDAL MIXING ON THE SEASONAL CYCLE OF THE SEA SURFACE TEMPERATURE IN THE INDONESIAN SEAS

A numerical model is used to investigate how the Indonesian Throughflow (ITF) and tidal mixing are affecting the seasonal cycle of the Sea Surface Temperature (SST) in the Indonesian
Seas. We find the ITF to play a major role on establishing a region of weak variability in the west and along the Nusa Tenggara parts of the Indonesian Seas. During Austral summer, the ITF warms the SST when the Northwestern Monsoonal wind would otherwise cool the SST through coastal upwelling. This results in weak SST variability and hydrographic observations support such heat balance in the western half of the Indonesian Seas. Tidal mixing is found to cool the SST during austral summer and winter. The Monsoonal winds are stronger in these seasons and the upper thermocline water, which is more effectively cooled by tidal mixing because of its stronger stratification, upwells to the surface. The Northwestern Monsoonal wind during summer also spreads the cooled SST water around the interior of the Indonesian Seas through Ekman transport and enables the strong impact of tidal mixing felt throughout the Indonesian Seas. PHYTOPLANKTON GROWTH IN THE AUSTRALIAN SECTOR OF THE SOUTHERN OCEAN, EXAMINED BY OPTIMISING ECOSYSTEM MODEL PARAMETERS.

The HNLC regime of the Southern Ocean is potentially important in controlling ocean-atmosphere CO2 fluxes. The causes of HNLC conditions has been the subject of much debate, with much attention focussing on availability of iron. The phytoplankton photosynthetic parameters of a simple NPZD model were optimised at three sites in the Australian sector of the Southern Ocean, spanning the Sub-Antarctic Zone, the Polar Frontal Zone and the Antarctic Zone. The optimised parameters give a good fit to SeaWiFS chlorophyll data and realistic ecosystem dynamics. The optimisations indicate that phytoplankton growth rates in the PFZ and AZ are limited by some process not explicitly included in this model, with iron availability being the most likely candidate. The effect of changes in algal growth rates outweigh the effect of changes in photosynthetic efficiency on the biological model solution, thus differences to the ecosystem functioning caused by iron availability are of greater consequence than differences in surface irradiance and MLD. Based on these optimisations we support the contention that iron availability is a primary cause of the HNLC conditions in this region. (Abstract ID 10932)

TWO-DIMENSIONAL WATER SURFACE TOPOGRAPHY MEASUREMENTS IN THE FIELD WITH THE REFLECTIVE STEREO SLOPE GAUGE

A new optical instrument for the measurement of surface wave slope and height properties was recently developed at the University of Heidelberg. The abilities of this Reflective Stereo Slope Gauge (RSSG) to measure the two-dimensional surface topography will be demonstrated. The RSSG overcomes the usual inaccuracies of stereo triangulation at specular surfaces by using properly positioned artificial light sources. The stereo images of a water surface patch with a size of about 1 m$^2$ are filled with specular reflections that are very similar to sun glitter. An algorithm was developed that precisely determines the water surface elevation for all specular reflections and interpolates over image areas without visible reflections to yield two-dimensional surface topography. Results from both a test on a pier near Lamont-Doherty Earth Observatory and the OSSPRE 2011 expedition on the Kilo Moana in the Pacific Ocean are presented to demonstrate the wide range of environmental conditions under which measurements are possible. DECADAL VARIABILITY OF LABRADOR SEA WATER FORMATION INFERRED FROM CHLOROFLUOROCARBON TIME SERIES

For almost two decades we have chlorofluorocarbon (CFC) measurements from repeated hydrographic surveys spanning major parts of the subpolar gyre. The data set is extensive enough in space and time to create individual time series for key regions of the North Atlantic. The CFC-based time series reveal the formation history of different modes of Labrador Sea Water (LSW) since the early 1990s. Here, we investigate the temporal variability of CFC penetrating into the water layers associated with light and dense modes of LSW. We follow the propagation of the CFC signal in different modes of LSW from the formation region to the southern and eastern parts of the subpolar gyre by means of time series analysis in the respective regions. Interannual variability of CFC is in close agreement with changes in T and S. The correspondence of physical parameters and CFC is particularly well noted in the Labrador and Irminger Seas, the source regions of intermediate waters responsible for ventilating the deep ocean. Observed changes are discussed in the light of changing activity of deep convection in the LSW formation area throughout the years. (Abstract ID 10676)

TRANSCRIPTIONAL PROFILING OF IN SITU FIXED ZOOPLANKTON – TRANSCRIPTOME OF A COPEPOD DIAPAUSING IN THE OXYGEN MINIMUM ZONE

Marine invertebrates are exposed to low pO2 and high pCO2 in oxygen minimum zones (OMZs). We developed a strategy to study physiological acclimations to these conditions using an in situ fixation procedure combined with high-throughput transcriptome sequencing. Bioinformatic analysis of the respective transcriptomes then allows identification of acclimation (and adaptation) mechanisms to the respective conditions. We first compared diapausing copepods (Calanus borealis) from the Namibian OMZ (low pO2, high pCO2) with C. similis samples taken at the Ocean surface (high pO2, low pCO2). This first large scale transcriptome analysis of a marine organism, diapausing in the OMZ provides strong evidence for metabolic reduction, negative regulation of transcription and translation, as well as increased molecular replication and repair in diapausing copepods. Transporter activity, energy-, lipid-, amino acid- and carbohydrate metabolism, as well as digestion are enhanced in active animals. These results are largely consistent with expectations based on published physiological research of C. similis. Compared to active animals, a strong respiration rate reduction of 80 - 90 % and dominance of catabolic processes were observed for diapausing animals. Our results confirm that in situ fixation is a suitable strategy to study acclimations and adaptations to OMZ conditions. (Abstract ID 10217)

XCTD HYDROGRAPHIC MEASUREMENT DURING UNCLOS 2011 CRUISE

The importance of the Arctic Ocean circulation to the global thermohaline circulation has been recognized, but the circulation scheme of the Arctic Ocean is still highly uncertain. In August-September 2011, CCGS Louis S. St-Laurent had a cruise from the Canadian Arctic coast toward the Lomonosov Ridge in tandem with USGC Healy (UNCLOS 2011 cruise). During UNCLOS 2011 cruise, 78 hydrographic profiles were collected by expendable conductivity, temperature, and depth data acquisition and processing equipments (XCTD). Using these data, we examined distribution, characteristics, and mixing processes of these water masses in order to understand the circulation scheme of the Arctic Ocean. One of the interesting points is that Pacific-origin water masses can be found at the north of the Chuikhi Rise in September 2011, although no signal of these water masses was there in 2008 and 2009. According to the previous publications, Beaufort Gyre circulation was intensified in a recent couple of years. However, the XCTD data in 2011 might suggest a relaxation of the intensified circulation and a change of water mass distributions around the Mendeleev Ridge and the north-western Canada Basin. Interannual variability is discussed in the context of changes in atmospheric circulation pattern and recent sea ice reduction. (Abstract ID 11086)

SOUTHERN OCEAN FINESTRUCTURE: SPATIAL AND TEMPORAL VARIABILITY OF NEAR-INERTIAL WAVES AND MIXING

Over the first 3 years of the DIMES tracer release experiment, 12 finestructure profiling floats (EM-APEX) have been deployed both upstream and downstream of Drake Passage in the Antarctic Circumpolar Current. Initial conclusions from the upstream (Southeast Pacific) tracer diffusion have revealed mixing rates only moderately enhanced above the low values typically found in the deep ocean (e.g., 1-1.5 × 10^-3 ms^-1). The profiling floats have identified enhanced shear from downward-propagating wind generated near-inertial internal waves as primarily responsible for this enhancement, with the resulting diapycnal diffusivity profile inferred from shear finestructure decreasing away from the surface. In contrast, within and downstream of Drake Passage, diffusivities are an order of magnitude larger (2 × 10^-2 ms^-1 at the tracer isopycnal) and increase towards the bottom. The increase is due to a combination of (a) stronger wind forcing and near-inertial wave variability in Drake Passage and (b) topographically-generated lee waves and internal tides. Ongoing measurements and analysis of the DIMES results are focusing on these processes, as well as on improving the spatial and temporal description of the internal wave and mixing fields. (Abstract ID 12048)

A SYNTHESIS OF CARIBBEAN PROXY SEA SURFACE TEMPERATURE RECORDS SINCE THE LATE MEDIEVAL PERIOD

Accurate reconstructions of past climate variability are needed to help understand the causes of variability and to test data to check the validity of predictive climate models. Three records of Caribbean sea surface temperature (SST) from different paleoclimate archives have been combined to make a regional Caribbean sea surface temperature index that extends back to the year 1356 C.E. The signal to noise ratio can be raised by averaging, effectively canceling some of the non-climatic noise and local variability present in each proxy record. The Caribbean regional record correlates significantly with instrumental SST over the modern period and contains distinct late medieval and Little Ice Age temperature regimes similar to global and hemispheric temperature reconstructions, but of larger magnitude. Caribbean temperatures were ~0.6°C cooler during the Late Medieval period compared to the 20th century whereas the Little Ice Age was ~1.4°C cooler than the 20th century. The timing and magnitude of variability suggests that this region contributes significantly to the global mean conditions on centennial timescales, supporting modeling results indicating the global climatic importance of this region. THE ROLE OF TURBULENCE STRESS DIVERGENCE IN DECELERATING A RIVER PLUME

Turbulence controls the composition of river plumes through mixing and alters the plume's trajectory by diffusing its momentum. In this study, finely-resolved density, velocity and turbulence observations are used to quantify terms in the momentum budget in the Columbia River's near-field plume during ten tidal cycles that encompass both high and low river flow. Turbulent stress varies by 2-3 orders of magnitude, both within a given ebb and between ebbs with different tidal or river forcing. Inter-ebb stress magnitude is related to the strength of an ebb outflow: high-stress occurs during the peak flow of strong ebbs. At these times turbulence stress divergence balances plume deceleration. Furthermore, the deceleration time scale based on plume stress is less than the half tidal period (6h), indicating that stress divergence plays a fundamental role in decelerating the plume. (Abstract ID 12732)

PRELIMINARY FEASIBILITY STUDY OF CHARACTERIZING IN-FLOW IN A POTENTIAL TIDAL POWER SITE

Tidal Energy is a promising alternative energy resource. Tidal current turbines convert tidal energy into electrical power. An essential step in developing this technology is characterizing the flow environments in which turbines are deployed. Specifically, both mean flow and turbulence statistics are required. This study summarizes our recent effort to characterize the flow in a potential turbine deployment site in Puget Sound (Northern Admiralty Inlet) from an engineering point of view. In addition to their usefulness in site operation and assessment, these data can be used to produce numerical simulation tools which help turbine designers more accurately predict hydodynamic loads on their devices. This study will help accelerate the development of tidal energy technology. (Abstract ID 12852)

GLOBAL OCEAN TIDES FROM GRACE SATELLITE ACCELERATIONS

Models such as FES2004 are routinely used to remove the effects of global ocean tides from GRACE data, but errors in ocean tide models alias into monthly GRACE solutions. Fortunately, GRACE inter-satellite ranging data can be used to solve for these tides directly. Nine years of GRACE inter-satellite acceleration data are inverted using a mascon approach to solve for residual amplitudes and phases of major solar and lunar tides relative to FES2004. Uncertainty estimates are derived from tidal solutions over land, and by subtracting two independent solutions that each use 4.5 years of data. Ocean loading corrections are applied to facilitate comparisons with tide gauge data. (Abstract ID 11649)

ATMOSPHERIC EKMAN PUMPING ABOVE AN SST FRONT

The impact of midlatitude SST fronts on the atmospheric Ekman layer is examined in idealized experiments with the Weather Research and Forecasting (WRF) model. Bottom Ekman layer concepts are applied to the mechanisms proposed by Lindzen and Nigam (1987) and Wallace et al (1989), in light of satellite observations showing the sensitivity of wind stress, cloud cover, and precipitation to SST fronts. The role of stratified spinup in modifying the atmospheric response to SST fronts, yet to be explored, is of particular interest. (Abstract ID 10929)

AN APPLICATION OF OPTIMAL INTERPOLATION TO SATELLITE OBSERVED CHLOROPHYLL-A AND ITS SPATIAL-TEMPORAL VARIATION

The East/Japan Sea which located in North-western Pacific shows high primary production due to its rapid turnover circulation. Related with global warming, the East/Japan Sea took a large attention as a potential carbon sink. Recent development of the satellite ocean remote sensing technology made wide area monitoring of chlorophyll-a with high resolution and high frequency available. Still, blank satellite data due to atmospheric condition is a problem to be solved. We filled the blank data using optimal interpolation method and analyzed reconstructed data. Chlorophyll-a data in the East/Japan Sea were achieved from July 2002 to July 2011. Using the data, spring and fall bloom initiation timing and location were identified and its spatial and temporal variations were analyzed. (Abstract ID 10905)

TIDAL EFFECT IN PREDICTIONS OF OIL SPILL TRAJECTORIES IN THE YELLOW SEA

The Hebei Spirit oil spill accident on 7 December 2007 was economically one of the largest ocean disasters in the Korea. Multi nested prediction system for the YS using the Regional Ocean Modeling system (ROMS) has been developed to predict the movement of oil spill for the Hebei Spirit. A suite of nested computational domains is implemented from the Northwest Pacific model to the coastal zones of interest. The oil spill trajectories at the surface predicted by model considering tide were comparable to the observation for one month experiment, whereas the trajectories predicted without tide is remarkably faster than the observation. The bottom current flowing northward without tide is also faster than that with tide in the interior of the YS. Increased bottom friction by strong tidal current results in decrease of vertical shear between the surface and bottom currents, whereas the relatively active bottom northeaster current which could act as a compensation flow may enhance the surface current without tide. Strong tide might reduce upwind flow and recirculation in the YS. In tide dominant area such as the YS, tide must be included to predict accurate trajectory not only for tidal period but also longer period. (Abstract ID 10874)

PHYSICAL AND BIOLOGICAL RESPONSES DURING THE 2009-2011 ENSO EVENTS IN THE SOUTHERN CALIFORNIA CURRENT

Atmospheric teleconnections of tropical El Niño [La Niña] events typically generate cyclonic [anticyclonic] wind anomalies in the northeast Pacific, which result in weakening [strengthening] of coastal upwelling in the California Current. The high resolution NCEP North American Regional Reanalysis (NARR) dataset confirms that upwelling favorable winds...
weaken in spring/summer 2009, the onset of the 2009-2010 El Niño, and strengthen in spring/summer 2010, the onset of the 2010-2011 La Niña. Consequent changes in chlorophyll (CHL) were observed in summer 2009, the onset of the 2009-2010 El Niño, and strengthen in spring/summer 2010, the onset of the 2010-2011 La Niña. Details of the link between physical forcing and primary production will be examined using continuous multidisciplinary mooring data in addition to NARR and remote sensing data. (Abstract ID 11505)

NEURAL NETWORKS ON THE OCEAN EFFECT ON HURRICANE INTENSITY

We investigate the oceanic effect on hurricane intensity numerically using Hurricane Weather Research and Forecasting (HWRF) model. An initial approach taken is a comparison of simulated hurricane intensities from non-coupled HWRF where sea surface temperature is held constant in time, and from coupled HWRF to the 3D HYCOM (Hybrid Coordinate Ocean Model). Analysis of 77 forecasts for Hurricane Gustav 07L (2008) and Ike 09L (2009) showed that a full interactive ocean coupling reduces the positive intensity bias by 20 – 25% than the non-coupled simulation. Both the coupled and non-coupled simulations used the same surface flux formulations implemented in HWRF, to compute momentum and enthalpy fluxes. In the first part of the presentation, we will explore the sensitivity of the HWRF-to-HWRF parameterization. The second part will present an analysis of experiments designed to address the following questions: 1. How does sea surface temperature variability encountered by translating footprint of the hurricane affects intensity? 2. Under what circumstances is the ocean feedback significant?; and 3. What are the necessary attributes of a coupled model to represent adequately a hurricane? (Abstract ID 11792)

VARIABILITY OF SUMMERTIME DENITRIFICATION RATES AT THE...

We present the result of temporal variation of the denitrification rates at the “Dead Zone” of the northern GOM during July 1995–2007 (except for July of 1988–1990), estimated by the extended Optimum Multi-parameter (OMP) analysis. The estimated denitrification rates at the bottom waters (<1 m above the sea floor) range from 1.36±0.58 to 7.40±4.17 Gg N mon⁻¹ (only for the July and for the mean study area of 3.2±10¹⁰ m²). The denitrification rates have gradually decreased from 1985 to 1997, and then increased during the 1998-2007 period, with somewhat large variation. The bottom waters on the Texas-Louisiana inner shelf were mainly composed of Texas-Louisiana Coastal Water (TLCW) and Subtropical Underwater (SUW), with much smaller volume contributions from the Mississippi and the Atchafalaya Rivers. Our results indicate that the composition of TLCW for the bottom water has increased gradually by as much as ~25% since ~1997, and this appears to have influenced the increase of benthic denitrification rates in the study area. The benthic denitrification rates at the bottom water of the northern continental shelf of GOM are not only influenced by the organic matter supply (biogeochemical factor: remineralization), but also by the relative contribution from different water masses (e.g. TLCW vs. SUW) to the area (physical factor: stratification). DISOIILED ORGANIC CARBON (DOC) IN THE SOUTHWESTERN EAST/JAPAN SEA

In the summer of 2008 and 2011, the vertical and horizontal distributions of dissolved organic carbon (DOC) were measured in the southwestern East/Japan Sea (EJS). In 2008, the concentrations of DOC ranged from 58 to 104 μM in the upper 200 m, and 54 to 66 μM in the deep water (200 – 1500 m) which were higher than those in the major oceans. A correlation between apparent oxygen utilization (AOU) and DOC in the deep ocean of the EJS revealed that the contribution of sinking DOC to the total biological degradation is relatively small (<10%). In a warm eddy region occurred in the upper 0 – 20 m in 2011, the concentrations of DOC were similar to those observed in 2008, while the concentrations of total dissolved nitrogen were lower toward the eddy center. The concentrations of DOC in the surface layer were unusually higher than those in the subsurface layer in these two periods, which seem to be due to the significant inputs of terrestrial DOC from the land. SPATIAL AND TEMPORAL PATTERN OF RIVER FLOW AND VERTICAL STRATIFICATION ACCORDING TO SEA GATE OPERATION IN THE YEONGSAN RIVER, SOUTH KOREA

Eutrophic circulation system has been changed in Yeongsan-river estuary, South Korea, since the construction of sea-dike. The sea-dike blocked a tidal effect, and artificial freshwater discharge reduced the tidal flat area and estuary width. To understand vertical stratification formation mechanism, physical properties of water such as, river flow, current, salinity and DO was observed using ADCP and CTD for 13 hours on 10th and 15th, August 2011. The strong fresh water discharge took place on 10th August 2011, only Maximum current reached more than 3.0 m/s on the day of strong river discharge (10th). Even this strong discharge from sea-gate at upper region, the bottom water flow upstream (0.5m/s) so that obvious 2 layer system was formulated. Although downstream freshwater tried to transfer its momentum to bottom for mixing, the salinity in bottom water maintains 30psu for the whole period. Similarly, the distribution of DO at surface indicates higher concentration than bottom. When the freshwater is weak (15th, August 2011), salinity at surface is 24-26psu and 30psu at the bottom. Maximum tidal velocity is about 05m/s during the normal condition. (Abstract ID 12894)

OBSERVATIONS ON FRONTAL-SCALE SECONDARY CIRCULATION ASSOCIATED WITH DRIFTING SUBMESOSCALE EDDIES

Two episodic events of secondary vertical circulation associated with drifting submesoscale eddies are presented with submesoscale current [O(1) m depth] derived from shore-based high-frequency radars (HFRs) and in-situ vertical profiles of the current and temperature within the spatial coverage of HFRs. In order to detect eddies from surface current maps, the winding-angle based approach based on flow geometry is applied to the calculated stream function. A cluster of nearly-enclosed streamlines with persistent vorticity in time is identified as an eddy. About 700 eddies were detected for each rotation (clockwise and counter-clockwise) from two-year surface current observations. The two rotations show similar statistics with diameters in the range of 5 to 25 km and Rossby number of 0.2 to 2. They persist for 1 to 7 days with weak seasonality and migrate with a translation speed of 4 to 15 cm/s advected by background currents. Considering the local wind events and surface kinematic and dynamic quantities (velocity potential, stream function, divergence, vorticity, and deformation rates), the vertical movement of thermoclines are more related to drifting submesoscale eddies instead of local upwelling. INCREASING N ABBUNDANCE RELATIVE TO P IN THE NORTHWESTERN PACIFIC OCEAN DUE TO ANTHROPOGENIC NITROGEN DEPOSITION

The relative abundance of nitrate (N) over phosphorus (P) has increased significantly over the period since 1980 in the marginal seas bordering the northwestern Pacific Ocean, located downstream of the populated and industrialized Asian continent. The increase in N availability within the study area was mainly driven by increasing N concentrations, and was most likely due to deposition of pollutant N from atmospheric sources. Atmospheric N deposition had a high temporal correlation with N availability in the study area, except in selected areas wherein riverine N load may be of equal importance. The increase in N availability caused by atmospheric deposition and riverine input has switched extensive parts of the study area from being N-limited to P-limited. (Abstract ID 9822)

DISOIILED ORGANIC CARBON (DOC) AND NITROGEN (DON) IN THE EAST/JAPAN SEA

Vertical and horizontal distributions of dissolved organic carbon (DOC) and dissolved organic nitrogen (DON) were measured in the East/Japan Sea (EJS), a marginal sea of the Pacific, during four periods from 2007 to 2009. The concentrations of DOC (8 ± 6 μM) in the surface layer (upper 200 m) of the EJS fall into the range in the major oceans, but those (58 ± 4 μM) in the deep layer (200 – 5500 m) were significantly higher than those in the Pacific Ocean (34 μM). The EJS stores approximately 0.9 Pg (10¹² g) of potentially bio-reactive DOC, which is about 12% of the bio-reactive DOC pool in the entire Pacific Ocean. This strikingly large storage is likely due to their rapid deep-water overturning and low DOC re-mineralization rates in the deep EJS. In contrast, the concentrations of DON in the entire depth were lower than those
in the major oceans. These high DOC:DON ratios seem to be due to the preferential uptake of DON by picophytoplankton in this extremely N-depleted EJS environment. (Abstract ID 10994)

ON THE SELECTIVE REGIONAL RESPONSE OF THE ANTARCTIC CIRCUMPOLAR CURRENT FRONTS TO ATMOSPHERIC AND OCEANIC VARIABILITY

The Antarctic Circumpolar Current (ACC) is well known for its multiple bands with large meridional property gradients in the upper waters as well as narrow deep-reaching current cores. A revised 17-year time series (1992-2009) of altimeter data from CNES/CLS AVISO is analyzed to identify and trace the spatial distribution and temporal variability of the multiple ACC fronts and its southern boundary. Specific contours of sea surface height (SSH) closely follow the observed multiple bands of maximum SSH slope. Their correspondence to ACC fronts is validated in the South West Antarctic Ocean using concurrent high-resolution data from hydrographic stations and ARGO profiles. Jets associated with the Subantarctic, Polar and southern ACC fronts have all experienced large seasonal to interannual variability from hydrographic stations and ARGO profiles. together in 2010 to establish COSEE China. Our goals are to (1) improve ocean literacy and awareness at the K-12, public, and university levels, (2) foster relationships between ocean scientists and educators, both internationally and domestically, and (3) bring marine sciences to the forefront of national development strategies and promote its protection. In order to achieve this, we hope to partner closely with COSEE centers across the United States so that ideas may be exchanged. Each university (or region) will function as a branch office under the COSEE China network and develop localized outreach programs. National level outreach will be coordinated jointly by Xiamen University and Ocean University of China. In the long run, we will work with relevant governmental agencies to develop nation-wide standards for ocean science education. Here we provide an overview of COSEE China and examples of outreach programs being developed by the Xiamen branch, encouraging citizenry to “Think Blue.”
